Aims of the Series

The Encyclopedia of Earth Sciences Series provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists. These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. See the back of this volume for a current list of titles in the Encyclopedia of Earth Sciences Series.

Go to <http://www.springerlink.com/reference-works/> to visit the "Earth Sciences Series" online.

About the Series Editor

Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the Encyclopedia of Earth Sciences Series. He has been the Executive Director of the Coastal Education and Research Foundation and Editor-in-Chief of the international Journal of Coastal Research for the past 35 years. He is also the Series Editor of the Coastal Research Library (Springer). In addition to these duties, he is Distinguished University Professor Emeritus at Florida Atlantic University (FAU) (Boca Raton, Florida). He is a graduate of Oregon State University (Corvallis) and the University of Western Australia (Perth). Work experience includes the International Nickel Company of Australia (Perth), Coastal Planning & Engineering (Boca Raton, Florida), and Technos Geophysical Consulting (Miami, Florida). He has published numerous peer-reviewed technical research papers and edited or co-edited and contributed to many books. Dr. Finkl is a Certified Professional Geological Scientist (Arvada, Colorado), a Certified Professional Soil Scientist (Madison, Wisconsin), a Certified Wetland Scientist (Lawrence, Kansas), and a Chartered Marine Scientist (London). Academically, he served as a Demonstrator at the University of Western Australia, Courtesy Professor at Florida International University (Miami), Program Professor and Director of the Institute of Coastal and Marine Studies at Nova Southeastern University (Port Everglades, Florida) and Full Professor at FAU. During his career, he acquired field experience in Australia; the Bahamas; Puerto Rico, Jamaica; Brazil; Papua New Guinea and other SW Pacific islands; southern Africa; Western Europe; and the Pacific Northwest, Midwest, and Southeast USA. Dr. Finkl is a member of several professional societies including the Geological Society of America; Soil Science Society of America; Institute of Marine Engineering, Science and Technology; and the Society of Wetland Specialists. He is a recipient of the International Beach Advocacy Award (Florida Shore & Beach Preservation Association), Certificate of George V. Chilingar Medal of Honor (Russian Academy of Natural Sciences), and Lifetime Commitment to Coastal Science Award (International Coastal Symposium).

Founding Series Editor

Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

vi	CONTENTS	
Earth's Structure, Lower Mantle <i>Edward J. Garnero, Allen K. McNamara and James A. Tyburczy</i>	176	Earthquakes, Energy <i>Domenico Di Giacomo and Peter Borman</i> 288
Earth's Structure, Upper Mantle <i>Guust Nolet</i>	183	Earthquakes, Intensity <i>Gottfried Grünthal and Roger M. W. Musson</i> 292
Earthquake Lights <i>John S. Derr, France St-Laurent, Friedemann T. Freund and Robert Thériault</i>	189	Earthquakes, Intraplate <i>Prantik Mandal</i> 299
Earthquake Precursors and Prediction <i>Toshiyasu Nagao, Masashi Kamogawa and Seiya Uyeda</i>	193	Earthquakes, Location Techniques <i>Clifford H. Thurber</i> 301
Earthquake Prediction, M8 Algorithm <i>Alik Ismail-Zadeh and Vladimir Kossobokov</i>	204	Earthquakes, PAGER <i>David J. Wald, Kishor S. Jaiswal, Kristin D. Marano and Michael Hearne</i> 308
Earthquake Rupture: The Inverse Problem <i>Shamita Das</i>	208	Earthquakes, ShakeCast <i>Kuo-wan Lin, David J. Wald and Daniel Slosky</i> 312
Earthquake Sounds <i>Andrew J. Michael</i>	220	Earthquakes, ShakeMap <i>David J. Wald, C. Bruce Worden, Eric M. Thompson and Michael Hearne</i> 316
Earthquake Source Theory <i>Raul Madariaga</i>	224	Earthquakes, Strong-Ground Motion <i>Giuliano F. Panza, Cristina La Mura, Fabio Romanelli and Franco Vaccari</i> 321
Earthquake, Aftershocks <i>Mian Liu and Seth Stein</i>	229	Earthquakes, Volcanogenic <i>J. W. Neuberg</i> 329
Earthquake, Archaeoseismology <i>Klaus-G. Hinzen</i>	232	Electrical Properties of Rocks <i>Takashi Yoshino</i> 339
Earthquake, Focal Mechanism <i>Emile A. Okal</i>	236	Electrical Resistivity Surveys and Data Interpretation <i>M. H. Loke, D. F. Rucker, J. E. Chambers, P. B. Wilkinson and O. Kuras</i> 344
Earthquake, Foreshocks <i>Mian Liu</i>	241	Electromagnetic Methods, Imaging Magma Bodies <i>Kathryn A. Whaler</i> 350
Earthquake, Magnitude <i>Peter Borman</i>	243	Electromagnetic Pulsations and Magnetic Storms <i>G. S. Lakhina and B. T. Tsurutani</i> 354
Earthquakes and Crustal Deformation <i>Robert McCaffrey</i>	254	Electronic Geophysical Year <i>William K. Peterson, Daniel N. Baker, C. E. Barton, Peter Fox, Mark A. Parsons and Emily A. CoBabe-Ammann</i> 359
Earthquakes in the Himalaya <i>Dibyashakti Panda, Bhaskar Kundu and Vineet K. Gahalaut</i>	262	Energy Budget of the Earth <i>Jean-Claude Mareschal and Claude Jaupart</i> 361
Earthquakes on Oceanic Transform Faults, Unexpectedly Large <i>Shamita Das</i>	274	Energy Partitioning of Seismic Waves <i>Kalachand Sain</i> 368
Earthquakes, Did You Feel It? <i>David J. Wald, Vincent Quitoriano and James W. Dewey</i>	278	Equatorial Electrojet <i>Archana Bhattacharyya</i> 372
Earthquakes, Early and Strong Motion Warning <i>Richard M. Allen</i>	282	Fault Zone Guided Waves <i>Peter Eric Malin</i> 375

	CONTENTS	vii
Fiber Optic Distributed Strain Sensing for Seismic Applications <i>Thomas Reinsch, Philippe Jousset and Charlotte M. Krawczyk</i>	379	Geomagnetic Field, IGRF <i>Aude Chambodut</i> 500
Fiber-Optic Sensing in Geophysics, Temperature Measurements <i>Jan Henninges and Ali Masoudi</i>	384	Geomagnetic Field, Measurement Techniques <i>Mioara Manda and Anca Isac</i> 502
Floating Seismographs (MERMAIDS) <i>Yann Hello and Guust Nolet</i>	395	Geomagnetic Field, Polarity Reversals <i>Carlo Laj</i> 507
Fractal Scaling of Earthquakes <i>Simanchal Padhy and Vijay P. Dimri</i>	399	Geomagnetic Field, Secular Variation <i>Monika Korte</i> 514
Fractals and Chaos <i>Ravi P. Srivastava, Nimisha Vedanti and Vijay P. Dimri</i>	405	Geomagnetic Field, Theory <i>Friedrich H. Busse</i> 515
Free Oscillations of the Earth <i>Sarva Jit Singh and Sunita Rani</i>	412	Geomagnetically Induced Currents <i>G. S. Lakhina, R. Hajra and B. T. Tsurutani</i> 523
Geodesy, Figure of the Earth <i>Kusumita Arora</i>	423	Geophysical Well Logging <i>Miroslav Kobr</i> 527
Geodesy, Ground Positioning, and Levelling <i>Stelios P. Mertikas</i>	427	Geothermal Heat Pumps <i>Ladislaus Rybach</i> 537
Geodesy, Networks, and Reference Systems <i>Hayo Hase</i>	434	Geothermal Record of Climate Change <i>Michael G. Davis, David S. Chapman and Robert N. Harris</i> 541
Geodesy, Physical <i>V. Chakravarthi</i>	442	GPS, Data Acquisition, and Analysis <i>Carine Bruyninx, Wim Aerts and Juliette Legrand</i> 547
Geodetic Pendulums, Horizontal Ultra Broad Band <i>Carla Braitenberg</i>	447	GPS, Tectonic Geodesy <i>Jeffrey T. Freymueller</i> 558
Geodynamics <i>Alessandro M. Forte</i>	452	Gravimeters <i>Andrew Hugill</i> 578
Geoelectromagnetism <i>Antal Adam and Laszlo Szarka</i>	454	Gravity Anomalies, Interpretation <i>Mikhail K. Kaban</i> 585
Geoid <i>Paramesh Banerjee</i>	465	Gravity Data, Advanced Processing <i>Christopher J. Swain and Jonathan F. Kirby</i> 591
Geoid Determination, Computational Methods <i>Michael G. Sideris</i>	470	Gravity Data, Regional-Residual Separation <i>Kumarendra Mallick, Vasanthi Anthwar and Krishna Kant Sharma</i> 596
Geoid Determination, Theory and Principles <i>Michael G. Sideris</i>	476	Gravity Field of the Earth <i>Christopher Jekeli</i> 608
Geoid Undulation, Interpretation <i>Petr Vaniček</i>	482	Gravity Field, Temporal Variations from Space Techniques <i>Anny Cazenave, J. L. Chen and G. Ramillien</i> 621
Geomagnetic Excursions <i>Martha Schwartz</i>	486	Gravity Field, Time Variations from Surface Measurements <i>Virendra M. Tiwari and Jacques Hinderer</i> 626
Geomagnetic Field, Global Pattern <i>Susan Macmillan</i>	488	Gravity Measurements, Absolute <i>Mark A. Zumberge</i> 633

viii	CONTENTS	
Gravity Method, Airborne <i>Uwe Meyer</i>	637	International Gravity Formula <i>Hans-Jürgen Götze</i> 789
Gravity Method, Principles <i>Hans-Jürgen Götze</i>	640	International Polar Year 2007–2008 <i>David J. Carlson</i> 790
Gravity Method, Satellite <i>G. Balmino</i>	645	International Year of Planet Earth <i>Eduardo F. J. de Mulder and Wolfgang Eder</i> 792
Gravity Method, Surface <i>Dinesh Chandra Mishra and Virendra M. Tiwari</i>	656	Inverse Theory, Artificial Neural Networks <i>William A. Sandham and David J. Hamilton</i> 796
Gravity Modeling, Theory and Computation <i>Jean-Pierre Barriot and Lydie Sichoix</i>	662	Inverse Theory, Global Optimization <i>Mrinal K. Sen and Paul L. Stoffa</i> 807
Gravity, Data to Anomalies <i>Ron Hackney</i>	668	Inverse Theory, Linear <i>Pravin K. Gupta</i> 814
Gravity, Global Models <i>Nikolaos K. Pavlis</i>	677	Inverse Theory, Monte Carlo Method <i>Malcolm Sambridge and Kerry Gallagher</i> 821
Gravity, Gradiometry <i>Christopher Jekeli</i>	692	Inverse Theory, Singular Value Decomposition <i>Ajay Manglik</i> 827
Great Earthquakes <i>Roger M. W. Musson</i>	708	Isostasy <i>A. B. Watts</i> 831
Heat and Ground Water Flow <i>Vincenzo Pasquale, Massimo Verdoya and Paolo Chiozzi</i>	717	Isostasy, Thermal <i>Derrick Hasterok and David S. Chapman</i> 847
Heat Flow Determinations, Continental <i>John H. Sass and Graeme Beardsmore</i>	722	KTB Depth Laboratory: A Window into the Upper Crust 855 <i>Ulrich Harms and Jochem Kück</i>
Heat Flow, Continental <i>Paul Morgan</i>	727	Legal Continental Shelf: Geology, Geophysics, and Tectonics 861 <i>Elana Geddis, Ray Wood and Vaughan Stagpoole</i>
Heat Flow, Seafloor: Methods and Observations <i>Earl E. Davis and Andrew T. Fisher</i>	736	Lithosphere, Continental <i>David E. James</i> 866
Height Systems, Vertical Datums and Their Unification <i>Michael G. Sideris</i>	749	Lithosphere, Continental: Thermal Structure <i>Claude Jaupart and Jean-Claude Mareschal</i> 872
High-Frequency Seismology <i>Simanchal Padhy</i>	757	Lithosphere, Mechanical Properties <i>Evgueni Burov</i> 884
Impact Craters on Earth <i>Richard A. F. Grieve and Gordon R. Osinski</i>	769	Lithosphere, Oceanic <i>James S. McClain</i> 893
Instrumentation, Electrical Resistivity <i>M. H. Loke, O. Kuras, J. E. Chambers, D. F. Rucker and P. B. Wilkinson</i>	776	Lithosphere, Oceanic: Thermal Structure <i>Earl E. Davis and David S. Chapman</i> 906
Instrumentation, EM <i>Steven Constable</i>	782	Lithospheric Magnetic Anomalies from Satellite Data 915 <i>Stavros Kotsiaros</i>
International Geophysical Year <i>Ralph W. Baird</i>	786	Magnetic Anisotropy <i>Leonardo Sagnotti</i> 923

About the Editor

Harsh K. Gupta is currently a member of the Atomic Energy Regulatory Board (India) and president of the Geological Society of India. He has previously been a member of the National Disaster Management Authority (India); secretary to the Government of India, Department of Ocean Development; director of the National Geophysical Research Institute, Hyderabad; vice chancellor of Cochin University of Science and Technology; and professor at the University of Texas at Dallas, USA. He is internationally respected for his work on artificial water reservoir-triggered earthquakes and developing criteria to distinguish them from normal earthquakes. As leader of the third Indian scientific expedition to Antarctica during 1983–1984, he succeeded in setting up India's first permanent Antarctic research station "Dakshin Gangotri" in just one Antarctic summer, which is still a record.

Prof. Gupta chaired the Steering Committee of the Global Seismic Hazard Program. After the disastrous 2004 Sumatra earthquake, he spearheaded the establishment of the Indian Tsunami Early Warning System. He has published over 200 articles in reviewed journals, authored 5 books that have been published by Elsevier and Springer. Prof. Gupta is a recipient of the Shanti Swarup Bhatnagar Prize, Waldo E. Smith Medal of American Geophysical Union, USSR Academy of Sciences "100 years of International Geophysics Memorial Medal," the Axford Gold Medal of the Asia Oceania Geosciences Society (AOGS), and the National Mineral Award of Excellence, among many honors. He is a fellow of the Indian National Science Academy, the World Academy of Sciences, and American Geophysical Union. Prof. Gupta has been president of the IUGG and the AOGS and is the founder president of the Asian Seismological Commission.

I. M. Artemieva
Marine Geodynamics
GEOMAR Helmholtz Center for Ocean Research
Kiel, Germany
and
Department of Geophysics
Stanford University
Palo Alto, CA, USA

Estella Atekwana
College of Earth, Ocean, and Environment
University of Delaware
Newark, DE, USA

Jonathan M. Aurnou
Department of Earth and Space Sciences
University of California
Los Angeles, CA, USA

E. V. S. S. K. Babu
Geochronology Division
CSIR-National Geophysical Research Institute
Hyderabad, India

Ran Bachrach
Geophysics and Planetary Sciences Department
Tel Aviv University
Tel Aviv, Israel

Ralph W. Baird
Baird Petrophysical International
Houston, TX, USA

Daniel N. Baker
Laboratory for Atmospheric and Space Physics
University of Colorado
Boulder, CO, USA

G. Balmino
Centre National d'Etudes Spatiales
Toulouse, France

Paramesh Banerjee
Earth Observatory of Singapore
Prayukti Geomatics Pte Ltd
Singapore, Singapore

Jean-Pierre Barriot
Observatoire Géodésique de Tahiti
University of French Polynesia
Faaa-Tahiti, French Polynesia

C. E. Barton
Australian National University
Canberra, ACT, Australia

Graeme Beardmore
University of Melbourne
Parkville, VIC, Australia
and
Hot Dry Rocks Pty Ltd
Windsor, VIC, Australia

David Bercovici
Department of Earth and Planetary Sciences
Yale University
New Haven, CT, USA

Jean Besse
Laboratoire de Paléomagnétisme
Institut de Physique du Globe de Paris
Paris, France

Archana Bhattacharyya
Indian Institute of Geomagnetism
Navi Mumbai, India

Jörg Bialas
Leibniz-Institut für Meereswissenschaften
University of Kiel
Kiel, Germany

Andrew Biggin
Geomagnetism Lab, Department of Earth, Ocean and
Ecological Sciences
University of Liverpool
Liverpool, UK

Joakim O. Blanch
BHP
Houston, TX, USA

Paul Bodin
Pacific Northwest Seismic Network (PNSN)
University of Washington
Seattle, WA, USA

Sigrid Böhm
Research Division Higher Geodesy, Department of
Geodesy and Geoinformation
TU Wien
Vienna, Austria

Marco Bohnhoff
GFZ German Research Center for Geosciences
Geomechanics and Scientific Drilling
Potsdam, Germany

István Bondár
Research Centre for Astronomy and Earth Sciences
Geodetic and Geophysical Institute
Kövesligethy Radó Seismological Observatory
Budapest, Hungary

Peter Borman
(Deceased)

Carla Braitenberg
Department of Mathematics and Geosciences
University of Trieste
Trieste, Italy

Laurie Brown
Department of Geosciences
University of Massachusetts
Amherst, MA, USA

Carine Bruyninx
Department of Reference Systems and Planetology
Royal Observatory of Belgium
Brussels, Belgium

Hans-Peter Bunge
Geophysics Section, Department of Earth and
Environmental Sciences
Ludwig Maximilians University of Munich
Munich, Germany

Evgueni Burov
(Deceased)

Friedrich H. Busse
Institute of Physics, University of Bayreuth
Bayreuth, Germany

Michel Campillo
Observatoire de Grenoble
Université Joseph Fourier and CNRS
Grenoble, France

David J. Carlson
British Antarctic Survey
IPY International Programme Office
Cambridge, UK

Richard W. Carlson
Department of Terrestrial Magnetism
Carnegie Institution of Washington
Washington, DC, USA

J. K. Catherine
CSIR-NGRI
Hyderabad, India

Anny Cazenave
LEGOS, Observatoire Midi Pyrénées
Toulouse, France

Vlastislav Červený
Department of Geophysics, Faculty of Mathematics and
Physics
Charles University
Praha, Czech Republic

R. K. Chadha
CSIR:National Geophysical Research Institute
Hyderabad, India

V. Chakravarthi
Centre for Earth, Ocean and Atmospheric Sciences
University of Hyderabad
Hyderabad, India

J. E. Chambers
Geophysical Tomography Team
British Geological Survey
Keyworth, Nottingham, UK

Aude Chambodut
Institut de Physique du Globe de Strasbourg
Université de Strasbourg/Ecole et Observatoire des
Sciences de la Terre, CNRS
Strasbourg Cédex, France

David S. Chapman
Department of Geology and Geophysics
The University of Utah
Salt Lake City, UT, USA

J. L. Chen
Center for Space Research
University of Texas
Austin, TX, USA

Paolo Chiozzi
Department of Earth, Environment and Life Sciences
University of Genoa
Genoa, Italy

Nikolas I. Christensen
Department of Earth and Ocean Sciences
University of British Columbia
Vancouver, BC, Canada

Ulrich R. Christensen
Max-Planck-Institut für Sonnensystemforschung
Göttingen, Germany

Annemarie Christophersen
GNS Science
Lower Hutt, New Zealand

Christoph Clauser
Institute for Applied Geophysics and Geothermal Energy
RWTH Aachen University
Aachen, Germany

Clarence S. Clay
(Deceased)

Sierd Cloetingh
Tectonics Group, Department of Earth Sciences
Utrecht University
Utrecht, The Netherlands

Emily A. CoBabe-Ammann
Research and Innovations Office
University of Colorado
Boulder, CO, USA

Steven Constable
Institute of Geophysics and Planetary Physics
Scripps Institution of Oceanography
La Jolla, CA, USA

Michele Cooke
Geosciences Department
University of Massachusetts at Amherst
Amherst, MA, USA

Vernon F. Cormier
Physics Department
University of Connecticut
Storrs, CT, USA

Vincent Courtillot
Institut de Physique du Globe de Paris
Paris, France

Stuart Crampin
British Geological Survey
Murchison House
Edinburgh, UK

Shamita Das
Department of Earth Sciences
University of Oxford
Oxford, UK

Earl E. Davis
Pacific Geoscience Centre
Geological Survey of Canada
Sidney, BC, Canada

Michael G. Davis
Department of Physical Sciences
Arkansas Tech University
Russellville, AR, USA

Paul M. Davis
Earth and Space Sciences
UCLA
Los Angeles, CA, USA

Eduardo F. J. de Mulder
Earth Science Matters Foundation
Haarlem, The Netherlands

Mike Dentith
School of Earth Sciences (M004)
The University of Western Australia
Crawley, WA, Australia

John S. Derr
Tijeras, NM, USA

James W. Dewey
U.S. Geological Survey, Denver Federal Center
Lakewood, CO, USA

Preface to the Second Edition

The oldest surviving encyclopedia is *Naturalis Historia* by Pliny the Elder, a Roman statesman in the first century AD. It has 37 chapters covering the history, geography, geology, and various other aspects of the world. In today's digital world of easy access to information, encyclopedias continue to be a valued source of reliable content contributed by experts. Subject encyclopedias contain in-depth entries offering essential and up-to-date information on the respective field of study, reflecting the current state of knowledge in the discipline as well as current trends. Encyclopedias published in electronic format are much easier to use than printed versions, given their search functions.

All information about the Earth's interior comes from field observations and measurements made within the top few kilometers of the surface, from laboratory experiments and from the powers of human deduction, relying on complex numerical modeling. Solid Earth geophysics encompasses all these endeavors and aspires to define and quantify the internal structure and processes of the Earth in terms of physical principles, corresponding mathematical formulations, and computational procedures. The role of solid Earth geophysics has gained prominence with increasing recognition of the fact that understanding Earth processes is central to the continued well-being of humanity. Apart from the exploration of natural resources, geophysical investigations provide crucial insights regarding the mutual relationships between climate and tectonics and on the effects of global change in terms of a broad range of natural hazards. The field continues to grow rapidly, both in fundamental and applied aspects, parallel to advances in allied fields of science and technology.

The second edition of the *Encyclopedia of Solid Earth Geophysics (ESEG)* serves as a comprehensive compendium of information on important topics in solid earth geophysics and provides systematic and up-to-date

coverage of central concepts and key topics of interest, while making no claims to represent every aspect of this multi-disciplinary and multi-faceted field. The earliest version of the *Encyclopedia of Solid Earth Geophysics*, edited by Prof. David E. James, was published by Van Nostrand Reinhold publishing company in 1989. The extraordinary growth and diversification of the field over the next 20 years called for a major revision. A completely new work, namely *Encyclopedia of Solid Earth Geophysics*, published by Springer in 2011, was edited by Harsh K. Gupta. It brought together over 200 entries covering established and new concepts in geophysics across sub-fields such as gravity, geodesy, geoelectricity, geomagnetism, seismology, seismics, deep earth interior and processes, plate tectonics, geothermics, and computational methods in a consistent format. Less than 10 years later, the need for an updated second edition was driven by the desire to expand the scope of the entries, which would include the new knowledge derived through novel observations and techniques. Consequently, this edition includes 256 entries written by 347 authors, and includes 44 new topics, such as Fiber Optics in Geophysics, Tracking Earth's Water in Motion, A New Era of Earth Observatories and Others Based on Satellite Observations, Deep Continental Boreholes Like the KTB, Seismic Arrays in Boreholes, Environmental Seismology, High-Frequency Seismology, Floating Seismographs, and several other new topics that have established themselves in recent years.

The entries, written by leading experts, are intended to provide a holistic treatment of solid Earth geophysics and guide researchers to more detailed sources of knowledge should they require them. A basic understanding of solid Earth geophysics is essential for professionals in many allied disciplines, such as civil engineering, environmental sciences, and the mining, exploration and software Industries, and for NGOs working on large-scale social agendas,

etc. This encyclopedia offers readers an authoritative and up-to-date reference source of extraordinary scope, drawing its unique strength from the contributions prepared by experts from around the globe.

2021 is the diamond jubilee year of the creation of the National Geophysical Research Institute, Council of Scientific & Industrial Research (CSIR-NGRI), where I spent

a major part of my academic life. It is a pleasure to commemorate the diamond jubilee of CSIR-NGRI with the publication of the second edition of ESEG.

Harsh K. Gupta

Preface to the First Edition

All information about the Earth's interior comes from field observations and measurements made within the top few kilometers of the surface, from laboratory experiments and from the powers of human deduction, relying on complex numerical modeling. Solid Earth Geophysics encompasses all these endeavors and aspires to define and quantify the internal structure and processes of the Earth in terms of the principles of physics, corresponding mathematical formulations and computational procedures. The role of Solid Earth Geophysics has gained prominence with increasing recognition of the fact that knowledge and understanding of Earth processes are central to the continued well being of the global community. Apart from persistent search for natural resources, this research line is linked to basic investigations regarding the mutual relationships between climate and tectonics and on the effects of global change in terms of a wide spectrum of natural hazards. Consequently, the pursuit of this science has seen spectacular progress all over the world in recent decades, both in fundamental and applied aspects, necessarily aided by advancements in allied fields of science and technology.

The *Encyclopedia of Solid Earth Geophysics* aims to serve as a comprehensive compendium of information on important topics of Solid Earth Geophysics and provide a systematic and up-to-date coverage of its important aspects including primary concepts as well as key topics of interest. It, however, does not claim to chronicle each and every niche area that in reality is a part of this multidisciplinary and multi-faceted science. Neither does it attempt to describe the basic physics of matter and energy systems, which comprise the underlying tenets of geophysical research. The first edition of this Encyclopedia, edited by Prof. David James, was published in 1989 by the Van Nostrand Reinhold publishing company. The

extraordinary growth and diversification of this science over the last twenty years called for a complete revision. This is realized by identifying the necessary topics and bringing together over 200 articles covering established and new concepts of Geophysics across the sub-disciplines such as Gravity, Geodesy, Geoelectricity, Geomagnetism, Seismology, Seismics, Deep Earth Interior and Processes, Plate Tectonics, Geothermics, Computational Methods, etc. in a consistent format. Exceptional Exploration Geophysics and Geotechnical Engineering topics are included for the sake of completeness. Topics pertaining to near Earth environs, other than the classical 'Solid Earth', are not within the scope of this volume as it is felt that the growth of knowledge in these fields justify a dedicated volume to cover them.

Articles written by leading experts intend to provide a holistic treatment of Solid Earth Geophysics and guide researchers to more detailed sources of knowledge should they require them. As basic understanding and application of Solid Earth Geophysics is essential for professionals of many allied disciplines such as Civil Engineering; Environmental Sciences; Mining, Exploration and software industries; NGOs working on large scale social agenda; etc., it would be useful to them to have access to a ready and up-to-date source of knowledge on key topics of Solid Earth Geophysics. Hopefully, this Encyclopedia would prove to be an authoritative and current reference source with extraordinary width of scope, drawing its unique strength from the expert contributions of editors and authors across the globe.

I am grateful to Anny Cazenave, Kusumita Arora, Bob Engdahl, Seiya Uyeda, Rainer Kind, Ajay Manglik, Kalachand Sain and Sukanta Roy, members of the Editorial Board for their constant advice and guidance in developing

the framework of this Encyclopedia and help with the editorial work. I am equally grateful to all the authors who readily agreed to contribute and honoured the guidelines and time schedule.

Petra van Steenberg, Sylvia Blago, Simone Giesler and D. Nishantini from Springer were very co-operative. It has been a pleasure working with Springer.

Ms. M. Uma Anuradha provided extraordinary assistance in the preparation of this volume. My wife Manju and daughters Nidhi & Benu supported me through the entire project.

Harsh K. Gupta
Editor-in-Chief

Acknowledgments

It has been a great pleasure working on the second edition of the *Encyclopedia of Solid Earth Geophysics*. My thanks go to Springer, particularly Petra Van Steenbergen and Sylvia Blago, for requesting it less than 10 years after the release of the first edition in 2011. I am also grateful to Anny Cazenave, Kusumita Arora, Bob Engdahl, Seiya Uyeda, Rainer Kind, Ajay Manglik, Kalachand Sain, and Sukanta Roy, the members of the editorial board, for their constant advice and guidance in developing the framework for this encyclopedia and support with the editorial work. I am equally indebted to the 347 authors who readily agreed to contribute and adhered to the guidelines and schedule.

The manuscripts went through several iterations during their development, and at each stage, they were carefully reviewed by prominent experts in their respective fields,

numbering over 200 from all over the world. Please accept my heartfelt thanks.

Petra van Steenbergen, Sylvia Blago, and Johanna Klute from Springer were very co-operative throughout this project, while Santhiya Rajarathinam helped with printing the manuscripts. It has been a pleasure working with Springer on this endeavor.

M. Uma Anuradha provided extraordinary assistance in the preparation of this volume.

I gratefully acknowledge the support provided by the CSIR-National Geophysical Research Institute, Hyderabad, and the National Academy of Sciences, India.

Last but certainly not least, my wife Manju and daughters Nidhi and Benu gave their unflagging encouragement throughout the entire project.

Harsh K. Gupta

Absolute Age Determinations: Radiometric

Richard W. Carlson

Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC, USA

Definition

Radiometric dating uses the decay of naturally occurring radioactive elements to determine the absolute age of geologic events.

Introduction

Time is an essential datum in geology. Some geological processes, particularly those responsible for generating natural hazards, occur over time intervals that can be measured with conventional clocks. Most geologic processes, however, occur on timescales beyond human experience – thousands, millions, and even billions of years (see ► [“Continental Drift”](#), ► [“Continental Rifts”](#), ► [“Geodynamics”](#), ► [“Lithosphere, Continental”](#), ► [“Paleomagnetism, Magnetostratigraphy”](#), ► [“Paleoseismology”](#), and ► [“Plate Tectonics, Precambrian”](#)). For these, the chronometer of choice is radiometric dating, where the decay of naturally occurring radioactive elements is translated into time (Dickin 2005; Faure and Mensing 2005). In its application to geochronology, the most important aspect of radioactive decay is that it occurs at a known, constant rate, independent of environmental factors such as changing temperature and pressure, at least within the ranges of these parameters found outside the interior of stars.

Only 10 years after the discovery of radioactivity, the renowned physicist Ernest Rutherford measured the amount of helium in a uranium ore and derived an age of 500 million years

for the ore (Rutherford 1906). By 1913, radioactive dating of rocks had made important inroads into geologic investigations of Earth history (Holmes 1913). The discovery of isotopes, also in 1913, and the improvement of the instruments used to measure their abundance (mass spectrometers) over the next decades, allowed radioactive dating to be applied to an increasingly broad range of natural materials, and hence, geologic processes. This, in turn, facilitated the transition of isotopic measurements from physics to geology departments and established radiometric geochronology as a tool of widespread use in the geosciences in the years following World War II.

Radioactivity and the Systematics of Its Use as a Chronometer

Radiometric dating is based on the principle of nuclear transmutation, common to alchemy. Some elements have isotopes whose nuclei contain an unstable number of neutrons and protons. The instability is most often remedied by the ejection of material from the nucleus. Alpha decay involves the ejection of two protons and two neutrons (a 4-helium (^4He) nucleus or alpha particle). Beta decay occurs through loss of an electron from the nucleus, turning a neutron into a proton. Another form of radioactive decay involves the capture of an electron from those surrounding the nucleus, turning a proton into a neutron. All forms of radioactive decay also release energy, and are thus a heat source in Earth’s interior (see ► [“Radiogenic Heat Production of Rocks”](#) and ► [“Energy Budget of the Earth”](#)). The result of radioactive decay is that an isotope of one element is transformed into an isotope of another element. While the path from lead to gold does not occur naturally, if one waits long enough, radioactive decay will eventually transform all uranium and thorium into lead.

Table 1 lists the major radioactive nuclides that have been used for dating various geologic events. Naturally occurring radioactive isotopes are produced through four mechanisms:

Absolute Age Determinations: Radiometric, Table 1 Radioactive elements commonly used for absolute age determinations

Parent isotope	Production mechanism	Daughter isotope	Half-Life (Million years)
7-Beryllium (^7Be)	Cosmogenic	7-Lithium (^7Li)	53 days
210-Lead (^{210}Pb)	Uranium decay	210-Bismuth (^{210}Bi)	22.3 years
226-Radium (^{226}Ra)	Uranium decay	222-Radon (^{222}Rn), ^4He	1,622 years
14-Carbon (^{14}C)	Cosmogenic, bomb	14-Nitrogen (^{14}N)	5,730 years
231-Protactinium (^{231}Pa)	Uranium decay	227-Thorium (^{227}Th), ^4He	0.033
234-Uranium (^{234}U)	Uranium decay	230-Thorium (^{230}Th), ^4He	0.25
36-Chlorine (^{36}Cl)	Cosmogenic, bomb	36-Argon (^{36}Ar)	0.31
26-Aluminum (^{26}Al)	Cosmogenic, stellar	26-Magnesium (^{26}Mg)	0.73
230-Thorium (^{230}Th)	Uranium decay	226-Radium (^{226}Ra), ^4He	0.75
60-Iron (^{60}Fe)	Stellar	60-Nickel (^{60}Ni)	1.5
10-Beryllium (^{10}Be)	Cosmogenic, stellar	10-Boron (^{10}B)	1.6
53-Manganese (^{53}Mn)	Cosmogenic, stellar	53-Chromium (^{53}Cr)	3.7
107-Palladium (^{107}Pd)	Stellar	107-Silver (^{107}Ag)	6.5
182-Hafnium (^{182}Hf)	Stellar	182-Tungsten (^{182}W)	9
129-Iodine (^{129}I)	Stellar, cosmogenic	129-Xenon (^{129}Xe)	15.7
244-Plutonium (^{244}Pu)	Stellar	Various fission products	80
146-Samarium (^{146}Sm)	Stellar	142-Neodymium (^{142}Nd)	103
235-Uranium (^{235}U)	Stellar	207-Lead (^{207}Pb), ^4He	704
40-Potassium (^{40}K)	Stellar	40-Argon (^{40}Ar) 40-calcium (^{40}Ca)	1,270
238-Uranium (^{238}U)	Stellar	206-Lead (^{206}Pb), ^4He	4,469
232-Thorium (^{232}Th)	Stellar	208-Lead (^{208}Pb), ^4He	14,010
176-Lutetium (^{176}Lu)	Stellar	176-Hafnium (^{176}Hf)	35,700
187-Rhenium (^{187}Re)	Stellar	187-Osmium (^{187}Os)	41,600
87-Rubidium (^{87}Rb)	Stellar	87-Strontium (^{87}Sr)	48,800
147-Samarium (^{147}Sm)	Stellar	143-Neodymium (^{143}Nd), ^4He	106,000
190-Platinum (^{190}Pt)	Stellar	186-Osmium (^{186}Os)	450,000

1. Stellar nucleosynthesis where the very high temperatures and pressures present in stellar interiors fuse nuclei, creating new elements (Truran and Heger 2005).
2. Some radioactive elements decay into other radioactive elements. For example, 238-uranium requires eight alpha decays and six beta decays before it reaches stable 206-lead. Along the way, the decay steps include some isotopes with long enough decay lives to be useful in geochronology. These include ^{234}U , ^{230}Th , ^{226}Ra , ^{222}Rn , and ^{210}Pb .
3. High-energy cosmic ray particles collide with atoms in Earth's atmosphere or surface rocks with enough energy to cause nuclear reactions. For example, 14-carbon is created when 14-nitrogen in the atmosphere captures a neutron released by a cosmic ray interaction with some other atom. Other cosmic-ray-produced nuclides include ^{10}Be and ^{26}Al that are made by spallation, which occurs when an energetic cosmic ray proton simply breaks off a fragment from the nucleus of an atom with which it collides. Radioactive isotopes produced in these reactions are known as cosmogenic isotopes.
4. Above-ground detonations of nuclear bombs introduced into the environment substantial quantities of a number of radioactive species that have been used to investigate a number of atmosphere – Earth's surface exchange processes, and for tracing ocean water circulation.

The probability that a radioactive isotope will decay over any time interval is described by the equation:

$$-dN/dt = \lambda N \quad (1)$$

where N is the number of atoms of the radioactive species (parent isotope), t is time, and λ is the rate constant of the decay. Rate constants often are converted to “half-life”; the time needed for half of the radioactive species to decay. The half-life of a radioactive species is equal to $\ln(2)/\lambda$. Integrating Eq. (1) gives:

$$N = N_0 e^{-\lambda t} \quad (2)$$

where N_0 is the number of atoms present when $t = 0$. This equation can be used to determine ages if one has independent information on the initial abundance of the parent isotope. For example, in ^{14}C dating, if one assumes that the ratio of ^{14}C to stable ^{12}C is constant in the atmosphere, then one need only measure the present day $^{14}\text{C}/^{12}\text{C}$ ratio in a material that obtained its carbon from the atmosphere and use Eq. (2) in order to determine the material's age. The assumption of a constant atmospheric $^{14}\text{C}/^{12}\text{C}$ ratio is now known to be invalid because the production rate of ^{14}C in the atmosphere depends

on issues as diverse as sunspot activity and the varying strength of Earth's magnetic field (see ► [“Paleomagnetic Field Intensity”](#)). Various schemes have been used to correct ^{14}C chronology for variations in the atmospheric ^{14}C production rate including comparison with the carbon in tree rings dated simply by counting the annual growth rings (Friedrich et al. 1999) or, for longer time intervals, to growth rings in corals dated with ^{230}Th and ^{234}U (Fairbanks et al. 2005). Although the variations in ^{14}C production rate complicate ^{14}C dating, they potentially provide information on the variability of Earth's magnetic field, or sunspot activity, and how these parameters may affect Earth's climate (Bard and Frank 2006).

Because the initial abundance of the parent isotope generally is not known, most radioactive dating schemes measure the increase in the abundance of the decay product (daughter). If no atoms are lost, the abundance of the daughter isotope (D) increases with time at the rate described by:

$$D = N_0 - N = N(e^{\lambda t} - 1) \quad (3)$$

Thus, in an ideal situation where, for example, a mineral forms that contains radioactive ^{40}K , but no ^{40}Ar , the age of the mineral can be determined simply by measuring the abundance of ^{40}K (N) and ^{40}Ar (D) in the mineral after some decay interval has passed. In nature, perfect separation of parent from daughter isotope is rare, so if some atoms of the decay product are present initially (D0), then:

$$D = D_0 + N(e^{\lambda t} - 1) \quad (4)$$

Because mass spectrometers can measure isotopic ratios of some elements to precisions of 0.0005% whereas elemental abundances can only be determined to about 0.1–1% precision, Eq. 4, using the ^{238}U - ^{206}Pb decay scheme as an example, can be expressed as:

$$\left(^{206}\text{Pb}/^{204}\text{Pb}\right)_m = \left(^{206}\text{Pb}/^{204}\text{Pb}\right)_0 + \left(^{238}\text{U}/^{204}\text{Pb}\right)_m (e^{\lambda t} - 1) \quad (5)$$

where “m” stands for the measured ratio and λ is the decay constant of ^{238}U . Pb-204 is a stable isotope of lead. If two or more samples with different U/Pb ratios are formed at the same time with the same initial Pb isotope composition ($(^{206}\text{Pb}/^{204}\text{Pb})_0$), after some time has passed, plotting the measured $^{206}\text{Pb}/^{204}\text{Pb}$ for each sample against its $^{238}\text{U}/^{204}\text{Pb}$ ratio will produce a line, called an isochron, whose slope and y-intercept correspond to $(e^{\lambda t} - 1)$, and the initial $^{206}\text{Pb}/^{204}\text{Pb}$ ratio, respectively (Fig. 1a). Thus, the slope of an isochron provides the time when the samples on the line had the same Pb isotope composition. The U–Pb system is unique in that it contains two isotopes of U that decay into two isotopes of Pb.

Thus, an analogous Eq. (5) can be written for the decay of ^{235}U to ^{207}Pb . More importantly, the two equations can be combined to give:

Absolute Age Determinations: Radiometric, Fig. 1 Isochron diagrams for the long-lived ^{147}Sm - ^{143}Nd and short-lived, now extinct, ^{146}Sm - ^{142}Nd systems. The data shown are for minerals separated from the Binda eucrite, a type of meteorite that is a volcanic rock erupted on some small planetesimal. The meteorite consists primarily of the minerals plagioclase and pyroxene, which have different ratios of Sm to Nd

when they form, but the same initial Nd isotopic composition. As Sm decays, it changes the isotopic composition of Nd. Using an equation similar to 5, the slope on the ^{147}Sm - ^{143}Nd diagram directly provides the age of the sample, but on the ^{146}Sm - ^{142}Nd diagram the slope provides the initial abundance of ^{146}Sm (actually the $^{146}\text{Sm}/^{144}\text{Sm}$ ratio as illustrated in an equation analogous to Eq. 8). Data from Boyet et al. (2010)

$$\frac{\left(\frac{{}^{207}\text{Pb}}{{}^{204}\text{Pb}}\right)_m - \left(\frac{{}^{207}\text{Pb}}{{}^{204}\text{Pb}}\right)_0}{\left(\frac{{}^{206}\text{Pb}}{{}^{204}\text{Pb}}\right)_m - \left(\frac{{}^{206}\text{Pb}}{{}^{204}\text{Pb}}\right)_0} = \frac{\left(\frac{{}^{235}\text{U}}{{}^{238}\text{U}}\right)(e^{\lambda_5 t} - 1)}{(e^{\lambda_8 t} - 1)} \quad (6)$$

where λ_5 and λ_8 are the decay constants for ${}^{235}\text{U}$ and ${}^{238}\text{U}$, respectively. Because the ${}^{235}\text{U}/{}^{238}\text{U}$ ratio is nearly constant in nature at any given time, this equation allows an age to be determined from measurements of lead isotopic composition alone, without the need for concentration determinations of U or Pb. Such ages, called Pb–Pb ages, are obtained by plotting $\left(\frac{{}^{207}\text{Pb}}{{}^{204}\text{Pb}}\right)_m$ versus $\left(\frac{{}^{206}\text{Pb}}{{}^{204}\text{Pb}}\right)_m$, which will produce a line for two or more samples whose slope is equal to the right hand side of Eq. (6). This equation can then be solved numerically to determine “ t ”, the time when the samples formed.

A very active application of radiometric chronology uses the variety of short-lived (half-lives of 10^5 – 10^8 year) radionuclides that were present when the solar system formed, but have long since decayed away (Carlson and Boyet 2009). For these systems, the “ t ” in Eq. (2) cannot be referenced to today because $e^{-\lambda t}$ would always be close to zero. Instead, the “ t ” for these extinct systems must be a time interval referenced to a time when the parent isotope still existed. In this case, using the decay of ${}^{26}\text{Al}$ to ${}^{26}\text{Mg}$ as an example, Eq. (5) can be rewritten as:

$$\left(\frac{{}^{26}\text{Mg}}{{}^{24}\text{Mg}}\right)_{\Delta t} = \left(\frac{{}^{26}\text{Mg}}{{}^{24}\text{Mg}}\right)_0 + \left(\frac{{}^{26}\text{Al}}{{}^{27}\text{Al}}\right)_0 \left(\frac{{}^{27}\text{Al}}{{}^{24}\text{Mg}}\right)_m e^{-\lambda \Delta t} \quad (7)$$

Plotting the two measurable parameters of this equation (${}^{27}\text{Al}/{}^{24}\text{Mg}$, ${}^{26}\text{Mg}/{}^{24}\text{Mg}$) for two or more samples will produce a line whose slope gives not the age, but the $\left(\frac{{}^{26}\text{Al}}{{}^{27}\text{Al}}\right)_0$ at the time when the samples formed (Fig. 1b). The time interval between the reference time and the time of sample formation is then:

$$\Delta t = -\left(\ln \left[\left(\frac{{}^{26}\text{Al}}{{}^{27}\text{Al}}\right)_{\Delta t} / \left(\frac{{}^{26}\text{Al}}{{}^{27}\text{Al}}\right)_0 \right]\right) / \lambda \quad (8)$$

To convert these relative ages into absolute ages requires cross-calibration with a chronometer that provides absolute ages. For example, a certain type of mineral inclusion within the Allende meteorite provided a Pb–Pb age of 4567.6 ± 0.4 Ma and an Al–Mg isochron whose slope corresponds to ${}^{26}\text{Al}/{}^{27}\text{Al} = 4.96 (\pm 0.25) \times 10^{-5}$ (Jacobsen et al. 2008). This provides a “pinning point” for the ${}^{26}\text{Al}/{}^{27}\text{Al}$ ratio present in the solar system at a known time. Thus, if analyses of some other sample produced an Al–Mg isochron whose slope corresponded to, for example, ${}^{26}\text{Al}/{}^{27}\text{Al} = 2.5 \times 10^{-5}$, this sample would be one half-life of ${}^{26}\text{Al}$, or 750,000 years,

younger than the other. Extinct radioactive dating systems thus provide not absolute, but relative, ages. If these relative ages are anchored to an absolute age, as done in the example above, then the extinct system can be used to indicate that the hypothetical sample mentioned above is 4566.8 million years old. A good example of the use of extinct radionuclides is the attempt to date the oldest volcanism in the solar system. Several types of meteorites are interpreted to be lavas produced on small planetesimals. One of these, the D’Orbigny meteorite, has provided Al–Mg, Mn–Cr, Hf–W, and Pb–Pb ages of ± 0.5 Ma, 4564.0 ± 0.6 Ma, 4562.8 ± 1.5 Ma, and 4564.42 ± 0.12 Ma, respectively. These results offer the promise of temporal precisions of 0.002% for the earliest events in solar system history.

The Application of Radiometric Dating

The relatively simple equations given in the previous section provide the basis by which measurements of radioactive decay products can be translated into absolute ages. Applying these chronometers to natural processes requires matching the distinct properties of the many radioactive systems listed in Table 1 to the problem being investigated. Systems with short half-lives can be used to determine precise ages of geologic events only a few to a few thousand years old. Many of these short-lived nuclides are created either in the atmosphere or upper meter of Earth’s surface, which makes them particularly amenable to dating a variety of near-surface processes. The concentrations of ${}^{10}\text{Be}$ or ${}^{26}\text{Al}$ in quartz in rocks or sediments can be used to date the time when the rock was exposed to cosmic rays, which can provide information on both uplift and erosion rates (von Blanckenburg 2005) (see ► “Paleoseismology”). The rates of water movement from surface through subsurface aquifers can be traced with a number of radiometric chronometers (Bethke and Johnson 2008). The presence of ${}^{10}\text{Be}$ in the lavas erupted at convergent margins tracks the subduction of surficial sediments to the 100 km + depths of magma generation (Morris 1991) (see ► “Subduction Zones”). Carbon-14 is used to date a huge variety of events from the eruption of young volcanoes, movement along faults (see ► “Earthquakes and Crustal Deformation”, ► “Earthquake, Archaeoseismology” and ► “Paleoseismology”), the rates of ocean water circulation and ocean uptake of atmospheric CO_2 , and the death of a living organism with its applications in archeology and paleoecology (Broecker 2005). The longer-lived radionuclides can be applied to a wide variety of issues concerning the evolution of the solid earth, from dating the formation of crustal rocks (see also ► “Paleomagnetism, Magnetostratigraphy”), to determining the time of continental assembly and breakup (see ► “Continental Drift” and ► “Plates and Paleoreconstructions”), to defining the age of the Earth.

The key point in the application and proper interpretation of radiometric dating is understanding exactly what event is being dated. What “starts” a radiometric clock is some event that changes the composition of a sample and fixes this new compositional state until the sample is dated in the laboratory. For example, ^{14}C often is used to determine the age of young volcanic eruptions. This system works in this application not by dating the rock itself, but by dating charcoal formed when the lava flowed over, and burnt, a bush or tree. What the ^{14}C age actually dates is the time when the plant stopped exchanging carbon with Earth’s atmosphere. In most cases, this happened because the plant was killed by the volcanic eruption, in which case, the ^{14}C age accurately dates the eruption. However, if a 100-year-old lava flow were to flow over a 10,000-year-old bristlecone pine tree trunk lying long dead on the ground, the ^{14}C date of the charcoal would be 10,000 years, not 100 years.

The precision of a radiometric age depends on the amount radioactive decay has changed the isotopic composition of the parent or daughter element. This depends primarily on the time passed relative to the half-life of the system, and in systems where measurement of the daughter element is involved, on the degree to which parent and daughter element are fractionated from one another. Thus, one would use ^{14}C with its 5,730 year half-life to date an organic remain from ancient Rome, but it would be useless to date a million year old limestone because the ^{14}C “clock” stopped measuring time when the ^{14}C decayed away after a few half-lives into the history of the limestone. Similarly, ^{147}Sm , with a 106 billion year half-life, is used to date a variety of materials ranging in age from millions to billions of years old, but would be useless to date very young processes because only 7×10^{-15} g of ^{143}Nd is produced every thousand years per ppm of Sm, and this amount simply is too small to measure accurately.

Besides choosing the proper radiometric system for the application, understanding whether a radiometric age is providing an accurate age for the event of interest demands an understanding of the processes that set, and reset, a radiometric clock. For Eq. (5) to provide an accurate age demands that the samples used to construct the isochron: (1) all formed at exactly the same time, (2) all had exactly the same initial daughter isotope composition, (3) experienced no change in parent/daughter element ratio between formation of the sample and its measurement in the laboratory, and (4) nothing other than the decay of the parent modified the daughter isotopic composition. In nature, all of these requirements have the potential to fail, but, in some cases, these “failures” can still provide useful information.

A good candidate to meet the requirements above is a volcanic rock. Under conditions ideal for an accurate age, a well-mixed magma will crystallize, over a short time interval after eruption, a variety of minerals with different parent/

daughter elemental ratios, but the same initial daughter isotopic composition that they inherit from the magma. Over time, if the minerals experience no chemical exchange with their surroundings, the radioactive decay products will build up allowing their measurement to provide the accurate age of eruption of this volcanic rock. The Apollo 15 basalt 15,386 provides evidence that when these criteria are met, ages from many radioactive systems can agree. For this sample, the age (in billions of years) obtained from different radiometric systems are: K-Ar 3.89 ± 0.04 , Rb-Sr 3.88 ± 0.01 , Sm-Nd 3.85 ± 0.08 , and the U-Pb age for zircon from a compositionally similar rock is 3.89.

For volcanic rocks this old, the assumption that the minerals all formed at the same time, at least relative to the ancient age of the rock, likely will be accurate. When one moves to younger volcanic systems, and the use of chronometers with better temporal resolution, the issue of the duration of crystallization becomes important. Several cases have now been presented where different minerals in the same volcanic rock give ages that range from the age of eruption to significantly older. One example is the Coso Volcanic field in California where zircons in one of the rhyolites range in age from the same as a K-Ar date on sanidine from the rhyolite, interpreted as the eruption age, to as much as 200,000 years older (Miller and Wooden 2004). This result suggests that emplacement and crystallization of distinct magma batches in the crustal magma chamber that eventually fed this eruption is a prolonged process occurring over many thousands of years. Similar results have now been reported in many young volcanic rocks (Cooper and Reid 2008). Although the age range of the minerals mentioned above is interpreted as reflecting a prolonged magmatic event, another way that an old crystal can get into a young magma is if a crystal from an older rock underlying the volcano is picked up by the magma during its ascent. Finding such “xenocrystic” material, particularly within more viscous, lower melting temperature, silica-rich magmas, is so common that it can be used to detect and even determine the age of older crust buried beneath a volcano, in some cases enabling the identification of older basement where none was previously known to exist (Smyth et al. 2007).

This brings up what is possibly the most insidious cause of an inaccurate radiometric age: the generally poorly-known temperature history of the sample. Because the rate of chemical diffusion within solids increases with temperature, elevated temperatures facilitate chemical changes. Heating a mineral can cause gases, such as He and Ar that are present in a crystal lattice as a result of their production through radioactive decay, to diffuse out of the crystal and escape along grain boundaries. At a temperature of 1,000 °C, diffusion will cause a Sr atom in a mineral to move about 2 mm in a million years. If a small grain of a high Rb/Sr ratio mineral, such as mica, is next to a grain of a low Rb/Sr ratio, and high

Sr content, mineral like plagioclase, the ingrowth of radiogenic ^{87}Sr in the mica will be diluted by diffusional exchange with the unradiogenic Sr in the plagioclase. Diffusion thus makes all radioactive chronometers “thermochronometers” that date the time when the material of interest reached a low-enough temperature to stop diffusional resetting of the radiogenic ingrowth. Because rates of diffusion are a function both of the element that is diffusing and the structure of the crystal through which it is diffusing, different radiometric systems, and different minerals, can have different sensitivities to temperature excursions. This gives rise to the concept of “closure” or “blocking” temperature, above which the diffusion rate is too high to allow for the buildup of the radioactive decay product. In other words, the radiometric clock does not start until the mineral falls below its closure temperature. In the Coso example above, the K–Ar age obtained for the sanidine is interpreted as the eruption age because even if this mineral formed well prior to eruption, the 200–400 °C closure temperature of the K–Ar system in sanidine (Fig. 2) is so low that the radiogenic ^{40}Ar being produced in the sanidine was diffusing out as fast as it was being produced because of magma temperatures in the range of ~750 °C.

In contrast, the closure temperature of the U–Pb system in zircon is higher than the magma temperature, so as soon as the zircon first crystallized, its U–Pb clock started to record time. Temperature-induced diffusional resetting of radiometric systems may make interpretations of ages a bit more difficult, but it creates a new field – thermochronometry – that constructs time-temperature histories for various geologic processes (Reiners and Ehlers 2005). Though many radiometric systems can be used for thermochronometry, the oldest radiometric dating technique, the decay of U and Th to He, has been reenergized (Farley 2002) because the low closure temperature of the U,Th – He system can be used to address geological processes such as the rate of mountain uplift or surface erosion by telling the time when a rock arrived close enough to Earth’s surface to cool below the closure temperature of the radiometric clock (Reiners and Brandon 2006).

While the appreciation and use of thermochronometry has been the primary growth field in radiometric geochronology in the last decade, other efforts are directed at finding ways to avoid reset ages. The traditional way to do this is to move to sample sizes much larger than diffusion lengths. This is the basis for “whole rock isochrons” where kilogram rock samples are homogenized and measured as an individual point on an isochron. Although this approach has produced some accurate ages, it suffers two main weaknesses. First, deciding whether all the rocks included on an isochron are the same age is not always easy, particularly for ancient, highly deformed, gneisses where this approach often is applied. Second, in order to obtain a sufficient range in parent/daughter ratio to precisely determine an isochron, compositionally distinct rocks are usually

Absolute Age Determinations: Radiometric, Fig. 2 Closure temperatures for various radiometric systems in different minerals. The fission track technique counts the density of damage tracks made in crystals due to the fission of ^{238}U . Coupled with the measurement of U concentration in the crystal, the density of fission tracks can be converted into a radiometric age. Figure modified from (Pollard, 2002 – <http://pangea.stanford.edu/~dpollard/NSF/main.html>) which was adapted from a figure produced by P. Fitzgerald, S. Baldwin, G. Gehrels, P. Reiners, and M. Ducea

included on the isochron. Judging from modern igneous rocks, large compositional distinctions often are associated with variable initial isotope composition, which would violate the requirement that all the samples used to construct an isochron have the same initial isotope composition. Where whole rock isochrons can be useful is in detecting when much older components are involved in the genesis of younger rocks. A good example of this are the Sm–Nd data for lunar basalts where mineral isochrons of individual samples provide eruption ages generally less than 4 billion years, but the whole rock data scatter about a line corresponding to an age near 4.45 Ga (Carlson and Boyet 2009). The precision of this older age is debatable, as is its interpretation, but it could imply that the younger basalts are made by melting source materials in the lunar interior that formed from some global differentiation event on the Moon that occurred some time near 4.45 Ga. Memory of this event was erased from the minerals in the

basalts, that know only of their crystallization from the magma, but the magmas themselves may “remember” the events that led to the formation of their source materials in the lunar interior.

The other approach to avoiding thermally reset ages is to use minerals whose crystal structure allows only very slow diffusion. One curious example is diamond. Diamond cannot be dated directly because it contains insufficient amounts of the radioactive elements, but it often contains as inclusions minerals that can be dated. Even though these minerals were formed, and have been stored, at temperatures above 1,000 °C and depths greater than 150 km in the mantle (see ► “[Lithosphere, Continental: Thermal Structure](#)”), the encapsulation by the diamond does not allow them to communicate through diffusion with their surroundings. As a result, dating of inclusions in diamond show that diamond formation in the mantle has occurred over a good part of Earth history, with the oldest diamonds being approximately 3.5 Ga (Pearson and Shirey 1999) (see ► “[Lithosphere, Continental](#)”).

By far, the most commonly used and most versatile way to avoid reset ages is with the application of the U–Pb system in zircon (Hanchar and Hoskins 2003). The strengths of U–Pb zircon dating include: (a) very high U–Pb closure temperature, (b) resistance to chemical modification through alteration and metamorphism, (c) high U concentrations, but initially vanishingly small Pb contents, (d) the U–Pb system includes two independent decay schemes that allow tests to determine whether or not the age has been disturbed (Wetherill 1956), (e) among the long-lived radioisotopes, the relatively short half-life of ^{235}U allows highly precise ages to be obtained for ancient rocks, (f) both the trace element concentrations and Hf isotope composition in zircon provide information on the nature of the source rock from which the zircon was derived, and (g) U–Pb ages can be obtained in samples as small as fragments of individual grains or even spots, tens of microns in diameter, ablated with either lasers or ion beams. Perhaps the only weakness of zircon is that it is not found in all rock types, occurring primarily in felsic igneous rocks. These characteristics explain the many varied applications of zircon U–Pb dating that include the discovery of the oldest dated material on Earth, 4.36 Ga zircons from quartzites in western Australia (Wilde et al. 2001), to high-precision calibration of the geologic time-scale (Bowring and Schmitz 2003), to the previously described use of zircons to determine the duration of crystallization in the magma chambers of young volcanic rocks.

Summary and Conclusions

Continually improving analytical capabilities coupled with expanding appreciation of the physical controls on what sets, and resets, radiometric clocks are allowing ever-increasing expansion of this now century-old approach. The

variety of radioactive species now in use provide the ability to determine absolute ages for geologic processes that occur over timescales that range from days to the age of the Earth and solar system.

Anthropogenic Seismicity Related to Exploitation of Georesources

Stanislaw Lasocki and Beata Orlecka-Sikora
Department of Seismology, Institute of Geophysics Polish Academy of Sciences, Warsaw, Poland

Definition

Anthropogenic seismicity: Earthquakes induced or triggered by technological, usually georesources exploitation-related, activity.

Overview

Exploitation of georesources alters the stress and strength conditions in the engaged rock mass. When such exploitation takes place in brittle rocks and yields stresses exceeding the rock strength at any point, the rock can fracture, violently emitting seismic waves. This anthropogenic seismicity was first observed as related to underground mining. The first

description of a damaging seismic event, called a rockburst, refers to the lead mine in Derbyshire in England in 1738. With rising demand for energy and minerals, anthropogenic seismicity has been appearing in association with diverse technological processes, and also in areas previously known as aseismic. Seismic events can be induced by underground and open-pit mining, both conventional and unconventional hydrocarbon exploitation, and geothermal energy production, as well as many other technological processes that perturb the boundary conditions in the affected rock mass (Fig. 1).

Although most of the induced seismic events are weak, hazards posed by anthropogenic seismicity can be significant. The severity of anthropogenic seismicity depends on the inducing technological activity. Figure 2 compares the largest seismic events induced by different georesources exploitation activities, respectively (source: The Human-Induced Earthquake Database (*HiQuake*), www.inducedearthquakes.org). The circled areas represent mutual proportions in the seismic energy of these events. All events presented here had significant damaging impacts.

Mechanisms of Interaction Between Technological Activity and the Rock Mass

A simplified mechanism of earthquake generation can be quantified by the Coulomb failure criterion (Fig. 3). Critical conditions leading to the seismic slip on a fault are met when the shear stress in the direction of slip, τ , equalizes the frictional strength of the fault, $\mu(\sigma_n - p) + c$, where σ_n is the compressive

Anthropogenic Seismicity Related to Exploitation of Georesources, Fig. 1 Georesources exploitation activities that induce seismicity

Anthropogenic Seismicity Related to Exploitation of Georesources, Fig. 2 The strongest seismic events induced by georesources exploitation. The circled areas represent mutual

proportions in the seismic energy of these events. (Source: www.inducedearthquakes.org)

Anthropogenic Seismicity Related to Exploitation of Georesources, Fig. 3 Scheme of conditions leading to seismic slip on a fault

stress normal to the fault plane, p is the pore pressure, c is the cohesion, and μ is the coefficient of friction. The term $(\sigma_n - p)$ is called the effective normal stress. The Coulomb criterion indicates that a fault can be brought to failure by reducing the normal stress, increasing the pore pressure, increasing the shear stress, decreasing frictional strength of the fault, or combinations of these factors.

Different georesources exploitation activities interact in different ways with a rock mass, inducing seismicity. The schematic mechanisms of these interactions are shown in Fig. 4 (McGarr et al. 2002). The mass transfer leading to empty spaces formation results in the possible simultaneous reduction of the normal stress and increase of shear stress during mining. The

volume contraction caused by the reservoir depletion in conventional extraction of hydrocarbons decreases the pore pressure. However, for certain orientations of nearby faults the contraction can also lead to a decrease of normal stress and an increase of shear stress on the fault, as is demonstrated in the lower part of Fig. 4. The pore-pressure increase is a primary seismicity-inducing factor for all technology using pressurized fluid injection, including secondary hydrocarbon recovery from conventional deposits, hydraulic fracturing for unconventional hydrocarbon production, underground disposal of liquid or gaseous wastes including carbon capture and storage (CCS) projects, enhanced geothermal systems (EGS), and underground storage of fluids and gases.

Anthropogenic Seismicity Related to Exploitation of Georesources,

Fig. 4 Schematic mechanisms of inducing seismicity by georesources exploitation. (After McGarr et al. 2002)

Induced, Triggered, or Natural

Anthropogenic seismicity, for which technological activity provides most of the stress/rock strength perturbations needed for its generation, is called induced seismicity. For seismicity known as triggered, anthropogenic stress/rock strength disturbances meet preexisting, preloaded faults and push these faults to failures. In such cases human activity accounts for only a small fraction of the energy associated with the earthquakes, whereas tectonic loading has the primary role.

The stress perturbations introduced by georesources exploitation are rarely capable of producing major earthquakes. Most of the severely damaging or devastating seismic events linked to technological activities are triggered. Because tectonic loading of preexisting faults increases with time, the fault pushed to rupture by a technological activity would have ruptured over time solely from increased tectonic loading, which would have occurred when the increasing shear stress on the fault plane had equalized the frictional stress. Moreover, if earthquake triggering is the result of an increase of pore pressure that weakens the fault, the triggered earthquake is weaker than the earthquake which would have occurred without the triggering technological activity. However, this realization is by no means comforting for people affected by the triggered earthquake.

When an earthquake has occurred within the range of technological operations related to the exploitation of georesources, the essential question is posed: did the technological activity

triggered this earthquake, or was it a natural event caused solely by tectonic forcing? An accurate answer to this question would determine the extent of responsibility of the company whose activities may have led to the earthquake. However, because the reaction of a rock mass to georesources exploitation is complex and diverse, in spite of numerous attempts (e.g., Davis and Frohlich 1993; Dahm et al. 2013; Zhang et al. 2016) there are no general recommendations that, when followed, would result in unequivocally answering this question. Moreover, even for individual earthquake cases studied in detail, debates on whether these are natural or human triggered may continue for years. Such are the sequence of earthquakes in Gazli, Uzbekistan (1976: M7, M7; 1978: M5.7; 1984: M7) possibly linked to conventional gas production; the case of the Coalinga, USA M6.5 earthquake in 1983, which might have been connected with oil production; the M5.1 Lorca, Spain earthquake in 2011, suspected to have been triggered by long periods of water pumping; and many others. Presently, it is often only possible to state whether human influence in the occurrence of a specific earthquake can or cannot be ruled out. This question was answered in the case of the sequence of devastating earthquakes that occurred in the Emilia-Romagna region, Italy, in May 2012. The sequence, with two main shocks of magnitudes approaching 6.0, killed 27 people, left more than 20,000 people homeless, and damaged or destroyed hundreds of structures of historical significance. The total loss has been estimated as some 5.4 billion euros. The general region as the Apennine foreland is seismically active, and this region has also had a long

history of georesources exploitation. In proximity to the earthquake sequence location, there were three active licenses for hydrocarbon production, one active gas storage concession, and one geothermal license. In the aftermath of the devastating earthquakes of May 2012, the Department of Civil Protection of Italy appointed an International Commission, ICHESE, to evaluate the possibility of an impact of these technological activities on the occurrence of the earthquakes (Styles et al. 2014). Analysis of the operational data from the hydrocarbon production license, the operation closest to the location of the earthquake sequence, showed that all parameters fluctuated, that is, monthly production of oil, monthly production of gas, average monthly reinjected volume of water, and average injection wellhead pressure. In particular, a rapid simultaneous change in trend from decreasing to increasing of monthly extracted and injected volumes of fluid and of the wellhead pressures occurred 1 year before the seismic crisis, in April–May 2011 (Fig. 5). This increasing trend lasted until the crisis in May 2012. Statistical tests indicated that the seismicity rate became greater in the period after April–May 2011, when all production parameters were increasing, than in the period before April–May 2011, when those parameters were decreasing. This result pointed to a link between technological operations in the area and the seismicity before the seismic crisis. At the same time the time–space clustering analysis indicated a strong connection between the seismic events that preceded the earthquake of May 20 and the subsequent major shock sequence. Furthermore, it was ascertained that the directions of the P and T axes within the group of events that occurred in the periods of increasing trends of operational parameters differed from the directions of these axes within the group of events that occurred in the periods of decreasing trends. The statistical analyses pointed also to the correlation between the P and T axes directions of events from the ‘increasing trends’

group with these axes directions of major shocks from May–June 2012. These observations indicated that the seismic activity within the time–space cluster of events which concluded with the May 20th main event was correlated with an increase of extraction and injection activity at the studied hydrocarbon production license.

The ICHESE commission also carried out geomechanical modeling of potential triggers for earthquake initiation. It has been recognized that the stress changes generated by the activities of reservoir depletion were not sufficient in themselves to initiate movement on the fault resulting in the earthquake of May 2012. Similar results from modeling were obtained later by various groups investigating the Emilia–Romagna seismic crisis. These results might be seen as arguing in favor of a tectonic origin of the whole earthquake sequence. However, the significant statistical correlations between the changes in seismic activity characteristics before the May 20, 2012 event and the increase in production parameters since April–May 2011 could not be ignored. Bearing in mind limitations of modeling, and possible discrepancies between the actual behavior of the Earth and the modeled behavior, the ICHESE commission has concluded that the combined anthropogenic actions of extraction and injection of fluids in a tectonically active region, already close to criticality, may have contributed to producing the conditions required to produce a significant earthquake (Styles et al. 2014). This example illustrates the possible difficulties in discrimination between natural and human-triggered seismicity.

Specific Features

Anthropogenic seismicity is by definition related to georesource exploitation. These relationships, the dependence

Anthropogenic Seismicity Related to Exploitation of Georesources,

Fig. 5 Fluctuations of average monthly reinjected volume of water and average injection wellhead pressure in the hydrocarbon production license, the closest to the location of the Emilia-Romagna earthquake sequence of May 2012. In April–May 2011 (marked by the vertical bar), the trend of these parameters changed from decreasing to increasing. This change yielded an increase of seismicity rate. (After Styles et al. 2014)

of seismic processes on technological processes, mean that some vital properties of anthropogenic seismicity differ from the properties of natural seismicity. Locations of anthropogenic seismic sources are in some ways linked to locations of the inducing factors. Therefore, these sources are mostly, although not exclusively, shallower than the sources of tectonic earthquakes. This shallowness results in strong shaking in epicentral areas caused even by events that are relatively weaker, and in fast decay of amplitudes of shaking with increasing epicentral distance.

Mining seismicity forms well-defined time–space clusters that are correlated in time and space with the time-varying location of mining work. Peak concentrations of seismicity locate at close distances ahead of mining work at and above unmined areas. Seismicity that is located at greater distances occurs mostly above the goaf and is usually linked to tectonic or mining discontinuities or weak zones. However, the detailed distribution of seismic events is mine specific. Fluid-injection- and fluid-extraction- induced seismicity are primarily related to the distribution of stress field changes in the subsurface surrounding the open hole of a well, the changes being caused by a combined effect of changes in pore pressure and changes in elasticity of the bedrock. Nevertheless, the distance at which earthquakes are triggered by fluid injection and the decay of seismic activity depend on the type of rock (Goebel and Brodsky 2018). In sedimentary rocks the pore pressure is transmitted to the surroundings more readily than in crystalline rocks. Consequently, induced seismic events extend further in sedimentary than in crystalline rocks. Moreover, in sedimentary rocks the seismic activity decays steadily with the distance from the injection point, whereas in crystalline rock the activity rapidly disappears beyond a certain distance.

Resulting from the complicated seismogenesis of anthropogenic seismicity, the source mechanisms of induced earthquakes, contrary to those of tectonic earthquakes, often have prevailing nonshearing components (e.g., Vavryčuk 2011). These components are on the one hand indicators of local modifications of the stress field induced by exploitation, but they depend also on local tectonics and the location of a source with respect to the geometry of technological operations. In mines the pure shearing mechanism is associated with either the slip across a preexisting fault or the slip associated with fracturing of intact rock. Events with such focal mechanisms result from stress changes induced by mining, but they are usually remote from excavations, and their focal mechanisms are controlled mostly by ambient stresses (McGarr 2005). The mechanisms composed of shear and implosive components result from strong interaction between the seismic events and the adjacent mine stope and involve combinations of fault slip and co-seismic stope closure. The mechanisms composed of deviatoric and explosive components are associated with time-dependent development of a fracture zone in the immediate environment of mining excavations (McGarr 2005). The most hazardous seismic phenomena in underground mines are rockbursts and tunnel collapses. Mining collapses are

very shallow, located on excavating levels not deeper than about 3 km. Being this shallow, they generate significant surface vibrations and rapid ground deformation. Typically, their mechanisms are mostly isotropic with a high (more than 50%) implosive element. It has been shown by Rudziński et al. (2016) that a collapse source can be modeled with a simple source model called tabular cavity collapse using diagonal moment tensor density with the nonzero elements $m_{11} = m_{22} = -1$ and $m_{33} = -3$ (Fig. 6).

Massive fluid injections and extractions cause spatiotemporal variations of crustal stresses on the reservoir scale, resulting also in diverse source mechanisms of injection-induced seismicity (Segall and Fitzgerald 1998). Tensile components of source mechanisms observed in injection-induced seismicity result from high pore pressure. Within hydrocarbon reservoirs, the least horizontal stress decreases with declining reservoir pressure caused by extraction, leading to a relative horizontal tension within the reservoir. In extensional environments, dilatant fracturing and normal faulting are always promoted near the edges of the reservoir or in regions of a high pore-pressure gradient. In regional compressional environments, production may trigger reverse faulting above and below the reservoir. In geothermal reservoirs, thermoelastic effects are also present and they even may dominate the poroelastic stresses, especially near injection wells and steam-producing fractures (Segall and Fitzgerald 1998).

Inducing technological operations continue only in a finite (from the human point of view) time period, and the operational parameters change with time. These time constraints cause time limitations and changes in time of the induced seismic processes. The time–space location of anthropogenic seismicity is transient. In contrast with tectonic earthquakes, by detailed insight the anthropogenic seismic processes can rarely be considered as stationary. Moreover, interactions among induced seismic events caused by co-seismic stress changes have been also identified in mines and in a geothermal reservoir (Orlecka-Sikora et al. 2012; Catalli et al. 2013). These stress changes influence the space–time patterns of seismicity.

The simplest, although quite efficient, approach to infer the time changes of seismic activity assumes that the event occurrences follow a nonhomogeneous Poisson process with a slowly changing event rate so that interval stationarity is an acceptable approximation. The event rate is then modeled by the Poisson distribution in which the probability of n events occurring in the time period $[t - \Delta, t]$ is $Pr[N = n] = \frac{[\lambda(t)\Delta]^n}{n!} e^{-\lambda(t)\Delta}$, where Δ is sufficiently small to allow for assuming the event rate, $\lambda(t)$, to be constant in this interval (Lasocki 2017 and references therein).

There are also attempts to include operational parameters of the inducing technology into models of induced events occurrence (e.g., Shapiro et al. 2010; Mena et al. 2013; Garcia-Aristizabal 2018). However, such models are so far very case-specific.

Anthropogenic Seismicity Related to Exploitation of Georesources, Fig. 6

Left: observed seismograms recorded on broadband stations after a strong mining collapse that occurred in Rudna Mine, Poland, in March 2013 (gray line) and synthetic (black line) traces generated for a tabular cavity collapse. Right: sketch of the contraction of a tabular cavity collapse and its source on the Hudson source-type plot. (By courtesy of Lukasz Rudziński)

With a less granular view of the problem, when seismicity is induced by a number of activities distributed in time and space (e.g., seismicity in a broader area with many operating injection wells), the impact of time changes of these individual factors may average itself, and the seismicity can present itself as stationary in longer time periods. However, even in such cases the anthropogenic event occurrence processes often deviate significantly from Poissonianity. For a Poisson process the interevent time (the time laps between two consecutive events) distribution is exponential, but observed interevent time distributions conform to Weibull or to even more complex distribution forms (e.g., SHEER Project, D4.2 2017).

The magnitude distribution models most commonly used in tectonic seismology stem from a statistical relationship known as the Gutenberg–Richter relationship. This relationship links linearly the common logarithm of the number of events observed in consecutive, same size magnitude bins, n , to magnitude values of the bin centers, m_m , $\log n = a - b \cdot \log m_m$ or the common logarithm of the observed number, N , of events whose magnitudes are greater than or equal to any m to m , $\log N = a - b \cdot \log m$. The relationship is obeyed above a certain completeness magnitude, m_c , which is the lowest magnitude of events, which are statistically all recorded

in given monitoring conditions. The Gutenberg–Richter relation leads to exponential models of magnitude distribution, either unlimited or with upper limits.

For the same reason as does the event rate, the distribution of magnitudes of anthropogenic seismic events also changes in time. Moreover, the variety of combinations of technological and geological factors inducing anthropogenic earthquakes may result in significant deviations of the observed magnitude distribution from the models derived from the Gutenberg–Richter relation. Such deviations have been statistically ascertained (e.g., Lasocki and Orlecka-Sikora 2008; Urban et al. 2016; SHEER Project D4.2 2017). The multimodality of magnitude distribution was indicated in some cases, which suggested the observed magnitudes to be mixtures of outcomes from different fracturing processes. Usually the deviations of observed magnitude distributions from the Gutenberg–Richter relation-based models are not dramatic and do not preclude the use of these models as handy approximations. Then, the changes in time of the slope parameter, b , must be taken into account. However, these deviations have significant consequences for seismic hazard assessment (Lasocki and Orlecka-Sikora 2008; Lasocki 2017 and references therein).

Collaborative Undertakings for Research into Anthropogenic Seismicity

Research into anthropogenic seismicity and related hazards requires an insight into relationships between the cause—the inducing technological activity, and the effect—the seismicity. Because of the complexity of induced seismic processes and the diversity and time-variability of the technological conditions responsible for generating the seismic events, these relationships are complex and difficult to quantify and generalize. Much progress in the understanding of these processes requires both deep integration of research groups active in the field and an access to high-quality data sets comprehensively describing both the inducing technological activity and the seismicity. In response to the increasing need for integration among scientists and engineers interested in induced seismicity, in 2007 the Triggered and Induced Seismicity Working Group (TAIS WG) was established in the International Association of Seismology and Physics of the Earth's Interior (IASPEI). The goal of TAIS WG has been to summarize the present state of knowledge on induced and triggered seismic processes and to discuss future trends in the field.

The discussions conducted within the TAIS WG inspired the creation of open-access services for studying anthropogenic hazards associated with exploitation of georesources. This goal has been realized by international teams in the form of the Thematic Core Service Anthropogenic Hazards (TCS AH) in the framework of the European Plate Observing System Program (EPOS-ERIC) (<https://tcs.ah-epos.eu>, Lasocki and Orlecka-Sikora 2016). The TCS AH consortium runs an e-research infrastructure, an IS-EPOS platform connected with the international data nodes that provides access to large sets of relevant data and allows free experimentation in a virtual laboratory. As well as its value for scientific work, the free access for all world researchers to this international facility enables proliferating discoveries and societal applications. The TCS AH consortium promotes interdisciplinary collaborations among all stakeholders: the scientific community, industrial partners, and society. The roadmap for TCS AH includes integrating worldwide research to develop capacities for addressing anthropogenic hazards challenges; further integrating and developing research infrastructures; increasing public understanding of anthropogenic hazards; driving innovation by transferring ready-to-use solutions to the industry; and transferring the expert knowledge and experience from industry to science.

Summary

In response to rising demands for minerals, exploitation of georesources is being carried out in more and more difficult stress conditions. As a result, the appearance of anthropogenic seismicity in the affected rock mass has been, and will be, increasing.

Most induced seismic events are weak; however, the hazard posed by anthropogenic seismicity can be significant. In particular, when perturbations in the rock mass caused by exploitation of georesources meet tectonically preloaded faults, the triggered seismic events can cause material loss, injuries, and even fatalities.

Exploitation of georesources often takes place in densely populated areas. Therefore, the accompanying seismicity is of socioeconomic significance. Although the hazard posed by anthropogenic seismicity is frequently overrated, public perception of these hazards and risks cannot be neglected. Vital georesources exploitation activities can lose public confidence unless the accompanying seismic risks are accurately assessed and properly presented to the public.

Anthropogenic seismicity results from and is in the first place related to the evoking georesource exploitation processes. In particular, because the exploitation activities change in time, anthropogenic seismicity processes and the related hazards are intrinsically time dependent.

The link of anthropogenic seismicity to the respective georesource exploitation activities suggests that potentially it is possible to maintain the anthropogenic seismic risk at an acceptable level by modifying operational practices. However, research into these cause–effect relationships requires multidisciplinary data collection with mandatory inclusion of relevant technological data. Further advances in the recognition of anthropogenic seismicity problems can be achieved only through problem-oriented international integration of the research groups active in the field and deep science–industry synergy.

Archaeomagnetism

Donald H. Tarling
School of Earth, Ocean and Environmental Sciences,
University of Plymouth, Plymouth, UK

Synonyms

Magnetic dating, archaeological; Remanence dating

Definition

Archaeomagnetism is the study of all remanent magnetization associated with materials found in, or associated with, an

archaeological context. In practice, it is the application of paleomagnetic techniques to archaeological materials, predominantly in terms of their uses in dating or “sourcing” such materials. This generally means that magnetic surveys are not usually considered “archaeomagnetic,” other than when used to provide information on the actual directions and intensities of the remanent magnetizations of the materials causing the anomalies.

As most applications of archaeomagnetic studies relate to magnetic dating, these aspects are described first.

Basic Features

Most materials within archaeomagnetic contexts contain iron oxide minerals that are capable of carrying a magnetic remanence acquired at some past time. More rarely, iron sulphides and hydroxides can carry such remanences. Even more rarely, a remanence can be carried by pure iron, nickel and cobalt and their alloys, and in very specific conditions, iron sulphates. The commonness of magnetite (Fe_3O_4) and hematite (Fe_2O_3) makes these almost always the dominant minerals involved. Such ferromagnetic (*sensu lato*) minerals can acquire a *thermal remanence* in the Earth’s magnetic field (or of nearby magnetic objects) while cooling from higher than ambient temperatures, *chemical remanences* as a result of crystalline or compositional changes. Some archaeological materials can comprise iron objects, but these are generally poor recorders of early remanences, being generally magnetically “soft.” All archaeological materials can become comminuted and eventually deposited as sediments (*v.i.* Archaeological sediments) in which the individual magnetic grains can be magnetically aligned during their deposition in aqueous or aeolian conditions, resulting in a *detrital magnetization* (see ► “*Paleomagnetism, Principles*” for details).

In an archaeological environment, it is unlikely that only one form of remanence is present. It can also be presumed that some of the originally acquired remanence will have decayed with time, and other time-dependent magnetizations, *viscous magnetizations*, will have been acquired as the materials lay within a geomagnetic field that gradually changes in both direction and intensity. In order to determine the direction and intensity of the geomagnetic field for some specific time in the past (such as when last heated or deposited), it is necessary to remove such viscous magnetization. Where such viscous magnetizations are not associated with chemical changes, they can be removed by partial demagnetization in alternating magnetic fields or heating in zero-magnetic field in nonmagnetic furnaces. Alternating field demagnetization randomizes the low coercivity components of remanence, that is, the viscous remanences, leaving the high coercivity components unchanged. Partial thermal demagnetization reduces the relaxation time of all contained minerals, that is, the time

taken for the direction of individual grain magnetization to relax into the ambient field direction. As the ambient field is zero, the grains with low relaxation times (those that carry the viscous magnetizations) thereby become randomized, leaving the high relaxation grains still in original directions. (For further detail, see ► [“Paleomagnetism, Principles”](#).) Such partial demagnetization procedures are necessary for magnetic dating using directions or intensity. Statistical analyses, initially Principle Component Analyses, are then made to determine the number, direction, intensity, and precision of the magnetic vectors present in any single sample (see ► [“Paleomagnetism, Measurement Techniques and Instrumentation”](#) for details). The isolated individual sample vectors defined within some 5° that are considered to have been acquired originally are then combined, usually using Fisherian Statistics and giving equal weight to each sample vector, to provide a mean site direction. (Where individual oriented hand samples have been subsampled, these subsamples are combined to obtain the sample values that then yield the site mean value.)

Such treatments normally require different instrumentation for dating based on directions than those for dating based on intensity and are described separately. The theoretical bases are the same.

Archaeological Site Sampling

Directional Analyses

Generally between 7 and 20 individually oriented samples are taken. This enables orientation errors to be averaged, as well as measurement errors. Ideally such samples are distributed evenly throughout the structure being sampled, although concentration is made on materials that are most likely to yield meaningful results and where the physical stability (since acquiring remanence) is better established. Sample orientation in situ is preferably undertaken nonmagnetically (sun compass, gyro-theodolite, or by sightings) as the objects themselves commonly distort magnetic compass readings. It is also desirable that the nature and conditions at the site, with the in situ samples, is recorded so that, when completing the analyses, possible causes from anomalous determinations can be better evaluated (see ► [“Paleomagnetism, Measurement Techniques and Instrumentation”](#)).

Paleo-intensity Analyses

Samples for such studies do not need to be oriented while in situ nor need the samples be still in their original positions in which their remanence was acquired. However, such orientations can be useful in assisting assessments of samples that show more than one remanent magnetic vector. Generally, some three to five samples are selected for study from any one archaeological site (see ► [“Paleomagnetic Field Intensity”](#)).

Magnetic Dating Based on the Direction of Remanence

This dating method depends on the longtime spatial variations (>~10 years) of the geomagnetic field (see ► [“Geomagnetic Field, Secular Variation”](#)). Analyses of the present-day geomagnetic variations suggest that, at a medium latitude location, the observed geomagnetic field in a circular area of some 550 km radius (~1 Mkm) can be modeled as that of a geocentric inclined dipole field within an error of ~0.5° (solid angle) in direction. At greater distances, the error increases to >1° (solid angle) rendering the model increasingly unreliable for comparing the directions of remanence at more distant sites. Such modeling enables “Master Curves” (Paleo-Secular Variation Curves) of directional change to be constructed using previously studied sites for specific regions, usually for a specific country or groups of small countries. In the UK, most English and Welsh observations were corrected to a central location, Meriden, while French observations were generally corrected to Paris.

Master Curves are now more commonly calculated within a far more sophisticated statistical modeling, notably hierarchical Bayesian modeling (Lanos et al. 2005). In such analyses, the Gaussian errors for the date assignments as well as for directional properties are incorporated in the construction of the Master Curves. Such Bayesian statistics similarly incorporate harmonic analyses. Spherical Cap analyses have the objective to determine the geomagnetic field variations attributable to fields at the Earth’s core (Pavón-Carrasco et al. 2008). The latter method is therefore more appropriate for geomagnetic field modeling (see ► [“Geomagnetic Field, Theory”](#)).

Relative Dating

Nearby sites (within some 50–80 km) that acquired their remanence at the same time will exhibit identical (within 1°) directions of remanence. Consequently, nearby sites with differing directions of remanence can be considered to have acquired their remanence at different times. Conversely, similar directions can indicate similar ages for their remanence acquisition. However, identical geomagnetic directions can occur in the same location at different times. When such repeat directions occur at time intervals of a few 100 years, the archaeological context is often adequate to distinguish between alternative age assignments.

Chronological Dating

This dating method is dependent on the secular variation of the geomagnetic field being known for the region being investigated (see ► [“Geomagnetic Field, Secular Variation”](#)). As the current geomagnetic theories for the origin of the geomagnetic field are still evolving (see ► [“Geomagnetic Field, Theory”](#)), this usually requires previously well-dated

(by non-archaeomagnetic means) site values to be available. In newly studied areas, the method is clearly inhibited by the lack of such data, but as more and more observations are obtained, the past directions of the geomagnetic field become increasingly well defined. Archaeomagnetic dating is thus an unusual scientific dating technique as its precision increases as more observations accumulate.

Magnetic Polarity and Polarity Excursion Dating

This dating application is based on unusual aspects of the long-term geomagnetic behavior. On scales of a few thousand years, the geomagnetic field can undertake major excursions away from its normal direction, geomagnetic events, or excursions. On timescales of a few 100,000 years, the Earth's magnetic field changes polarity – the North magnetic pole becoming the South magnetic pole, and vice versa for the South magnetic pole. Consequently, some geomagnetic excursions occur on archaeological timescales, and the younger polarity changes occur on archaeological-anthropological timescales (see ► [“Geomagnetic Excursions”](#) and ► [“Geomagnetic Field, Polarity Reversals”](#) for more detailed considerations).

Magnetic Dating Based on the Intensity of Remanence

Relative dating can be based on the determination of paleointensities of the ancient field in a similar way as for direction (qv). Most current studies are directed toward defining the changes in geomagnetic intensity during archaeological time although sufficient quantities of high quality paleo-intensity determinations are now becoming available for specific regions, enabling chronological dating to be undertaken. As for directional studies, when past records of the Earth's magnetic field intensity are available, a Master Curve can be constructed for a similar circular area of $\sim 1 \text{ Mkm}^2$, radius of $\sim 550 \text{ km}$, as for directional studies.

Errors

General Errors

These apply to both directional and intensity dating techniques.

1. It is usually assumed that any effects of weathering and other environmental changes are minimal and that the magnetic grains carrying the remanence of interest are essentially unaffected. However, some weathering products, such as goethite and hematite, can carry high-stability remanence. It is desirable that, as far as practicable, unweathered materials are collected.

2. During partial demagnetization, it is assumed that no chemical or structural alterations occur to the existing magnetic minerals and that no new magnetic minerals are formed. Such changes are far more likely during thermal demagnetization than by alternating magnetic field techniques and are usually monitored by repeated measurements of the initial susceptibility. This is, however, a coarse measure and magnetic domain changes (see ► [“Magnetic Domains”](#)) which can occur with no clear change in susceptibility.
3. Both directions and intensities can be affected by magnetic anisotropy (shape and crystalline) that may be associated with the sample shape, the shape of contained minerals and the orientations of their crystallographic axes (see ► [“Magnetic Anisotropy”](#)).
4. Lightning strikes at times subsequent to the original acquisition of remanence, and have electromagnetic effects that can drastically alter the magnetic remanence. Although mostly associated with electrical charges that usually travel through surface waters, these effects can penetrate. Such effects can usually be recognized by their high intensities and tendency to be in random directions.
5. The local geomagnetic field direction and intensity may well be distorted if there were nearby magnetized objects, natural or manufactured, at the time of remanence acquisition.
6. The behavior of the geomagnetic field is still poorly defined and, particularly at high magnetic latitudes, can show major diurnal variations. It also appears that secular variations are not necessarily smooth, but may occur in “jerks” (see ► [“Geomagnetic Field, Secular Variation”](#)) although these appear to be mostly within the current experimental error of the technique.
7. The geomagnetic field over time can return to previous direction and intensity values. When such “crossover” points occur in the Master Curves at sufficiently different times, then the archaeological age constraints on the site may enable the most likely chronological age to be applied. However, most extant Master Curves are likely to still be distorted by some studies for which the archaeological or chronological age has subsequently been modified. However, such “anomalous” sites becoming increasingly recognized as databases increase.

Errors Specific to Directional Dating

In addition to the general errors, directional studies are sensitive to the oriented samples having remained in situ since they acquired their remanences. In a solid structure, such loose materials can be readily identified, but individual parts of some structures can have undergone motions relative to the rest of the structure, for example, kiln-wall “fall-out” or “fall-in.” On hillside, it is also possible that the whole structure may have undergone motion away from where the remanence was

acquired. Thus, a knowledge of the archaeological controls on possible motions of the site is essential.

Errors Specific to Intensity Dating

In addition to the general errors, paleo-intensity studies are sensitive to the “cooling rate” of the acquired magnetic properties. The naturally acquired remanence will commonly have been acquired over times that can be of the order of several days, while the laboratory studies are necessarily on far shorter times scales. The laboratory redox conditions during cooling are normally very different.

Overall Error Assessment

While there are many potential sources of error in archaeomagnetic dating, in most archaeological sites where the conditions are clear and the materials largely pristine, the errors arising appear to be only rarely of sufficient magnitude to warrant rejection.

Specialized Applications

Murals and Plaster

Remarkably, it has been shown that pigments can carry a remanence relating to the time when they were applied. Where such pigments have been applied to walls, their remanence has been shown to relate to the time that the pigments were applied, particularly in tempera paintings – either originally or during subsequent retouching. It seems most likely that this remanence is associated with hematite and was acquired “detritally,” that is, by rotation of the grains while still fluidized (Lanza et al. 2009). Similar observations have also been shown for plaster work (Soler-Arechalde et al. 2006).

Object Reconstruction

Specific artifacts, such as pottery, when fired, obtain a uniform magnetization in the ambient geomagnetic field as they cool within the furnace. If broken, individual shards retain this original remanence and can be reassembled to assist in defining the original shape of the pot (Burnham and Tarling 1975).

Archaeological Sediments

As sediments are deposited within an archaeological site, any contained already magnetized grains are influenced by the ambient geomagnetic field. As these alignment forces are weak (compared with the effects of gravity and flow motions) only a percentage of the magnetic grains are aligned and such alignments can be gravitational flattening during the deposition process. However, the more magnetically stable grains (usually with single-domain dimensions of $\sim 1 \mu\text{m}$) can rotate into full alignment while they are still fluidized immediately after deposition. However, such alignments can be modified by meniscus

forces as the water table subsequently rises or falls. Sedimentary minerals also undergo a series of chemical reactions as they adjust to their new environment. Consequently, it is often difficult to establish the true direction of the geomagnetic field at the time of deposition with sufficient certainty to assign ages based on the magnetic determinations. However, there are archaeological sites, such as basal sediments, deposited immediately after a ditch had been cut, that appear to be recording the geomagnetic field direction at that time.

Magnetic “Sourcing”

Magnetic sourcing attributes an object to a particular location on the basis of its magnetic properties. For example, an obsidian arrowhead can sometimes be sourced to the obsidian outcrop from which it was originally fashioned.

The physical basis for this is that the compositions and grains sizes of the magnetic minerals within a rock can be specific to a particular outcrop. Each outcrop also tends to have a slightly different cooling history and became magnetized by a specific geomagnetic field strength. Several magnetic properties can be rapidly and cheaply measured, such as its initial (low field) susceptibility, its saturation remanence, and its intensity of natural remanence, are sufficient to identify a specific outcrop. Generally, the range of magnetic properties in most sedimentary rocks is too great to allow such assignments, but obsidians, rapidly cooled volcanic glasses, commonly have a range of magnetic properties that are either unique to that outcrop or to only two or three outcrops.

Summary

The study of the magnetic properties of archaeological materials, archaeomagnetism, is particularly significant in geophysics as it enables secular variations in the direction and strength of the geomagnetic field over timescale that are far longer than those for direct measurement (~ 400 years). In comparable magnetic studies of rocks, paleomagnetism, these secular variations are commonly averaged out during the processes by which rocks acquire their remanent magnetization. Conversely, archaeomagnetic records provide an additional dating tool for archaeologists. As a comparative dating tool, archaeomagnetism enables relative dating between nearby samples (100–200 km) within ~ 10 –20 years. As a dating tool, it is mainly dependent on the validity of the ages used to compile the regional Master Curve. It is thus unique, as a scientific dating method, in that as more data are acquired, age “outliers” can be identified and their age reassessed. Consequently, the Master Curves are continually improving and, ultimately, could have the same precision as for relative dating. There are also interesting applications in using such observations in conservation studies and establishing past environmental conditions.

Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India

Harsh K. Gupta

National Geophysical Research Institute, Council of Scientific and Industrial Research, Hyderabad, India

Definition and Introduction

Under certain suitable geological conditions, anthropogenic activity can trigger or induce earthquakes. The triggered/induced earthquakes are known to have occurred due to gold and coal mining, petroleum production, filling of artificial water reservoirs, high-pressure liquid injection into ground, geothermal energy, and natural gas production. The largest scientifically accepted triggered earthquake of M 6.3 occurred on 10 December 1967 in the vicinity of Koyna Dam near the west coast of India. It is debated

whether the M 7 Gazli earthquakes of May 1976 and 19 March 1984 were induced due to the production of large quantities of gas at the Gazli oil field in Uzbekistan. There is an argument that the Sichuan, China, M 7.9 earthquake of 12 May 2008, that claimed over 80,000 human lives, was triggered due to filling of the nearby Zipingpu reservoir. It has been also proposed that flooding of a river near San Andreas Fault in California caused at least two M~6 earthquakes. A good account of triggered/induced seismicity can be found in a review by (McGarr et al. 2002). Hudyma and Potvin (2005) and Drzewiecki and Piemikarczyk (2017) have extensively dealt with mining-induced seismicity. Gupta (2002) has reviewed artificial water reservoir-triggered seismicity.

Here we present cases of artificial water reservoir-triggered earthquakes that occurred all over the world, with a special emphasis on earthquakes in the Koyna region near the west coast of India. This is a classical case where triggered earthquakes have been occurring since the impoundment of reservoir in 1962 till now in 2019.

Triggered vis-à-vis Induced Earthquakes

For a long time, the adjectives “induced” and “triggered” were used interchangeably whenever one talked of artificially simulated earthquakes. McGarr and Simpson (1997) have addressed this question and suggested that it would be important to draw a distinction between the two. They proposed that the adjective “triggered seismicity” should be used only when a small fraction of stress change or energy associated with earthquakes is accounted for by the causative activity. The term “induced seismicity” should be used where the causative activity is responsible for a substantial part of the stress change. In the case of triggered seismicity, tectonic loading plays an important role. The stress-level changes associated with filling of some of the deepest artificial water reservoirs are only of the order of 1 MPa or so, whereas the stress drop associated with the earthquakes is much larger. Therefore, all cases of earthquakes occurring subsequent to filling of the artificial water reservoirs fall in the category of “triggered earthquakes,” and hence it is appropriate to call it “reservoir-triggered seismicity” (RTS).

Artificial Water Reservoir-Triggered Earthquakes

The generation of hydroelectric power, flood control, and irrigation has led to the creation of huge artificial water reservoirs globally. For the first time, triggering of earthquakes was pointed out by Carder (1945) at Lake Mead in the USA. Figure 1 depicts Lake Mead water levels and local seismicity for the period 1936 through 1944. The rise in water level and corresponding bursts of seismic activity are numbered. The correspondence is indeed remarkable. Damaging triggered earthquakes exceeding M 6 occurred at Hsingfengkiang, China (1962); Kariba, Zambia-Zimbabwe border (1963);

Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India, Fig. 1 Lake Mead water levels and the local seismicity. For 1936 and 1937, only the felt shocks are plotted. The

risers in water levels and the corresponding bursts of seismic activity are numbered. General trend of tremor-frequency variation is shown by dotted lines (After Carder 1945)

Kremasta, Greece (1966); and Koyna, India (1967). Koyna earthquake of M 6.3 that occurred on 10 December 1967 is so far the largest scientifically accepted triggered earthquake. It claimed over 200 human lives, injured about 1500, and rendered thousands homeless. The occurrence and potential of triggered earthquakes has caused major modification of civil works and engineering projects. Anticipating a large triggered earthquake, the Hsingfengkiang Dam was strengthened twice before the occurrence of M 6.1 earthquake on 20 March 1962 (Shen et al. 1974). The disposal of waste fluid through injection into the ground at the Rocky Mountain Arsenal had to be discontinued due to triggered earthquakes (Evans 1966). The possibility of high-magnitude-triggered seismicity was responsible for terminating the Auburn Dam project in California (Allen 1978). There is a general reluctance on the part of Engineering Community, globally, to accept the significance or even existence of the phenomenon of triggered seismicity (Allen 1982; Simpson and Leith 1988). What Allen (1982) said some four decades ago, “From a purely economic point of view, not to speak of public safety, the problem of reservoir induced earthquakes deserves far more attention than it currently is receiving in most parts of the world,” is still true.

Reservoir-Triggered Seismicity (RTS): Global Distribution

Globally there are hundreds of sites where RTS is reported to have occurred. Gupta (2011), on the basis of magnitude of the largest triggered earthquake, grouped these sites in the following categories (Table 1):

1. Sites where largest earthquake exceeded M 6.0 (4 sites)
2. Sites where the largest earthquake M was 5.0 to 5.9 (10 sites)
3. Sites where the largest earthquake M was 4.0 to 4.9 (29 sites)

Over the years, RTS has been reported from many more sites. Among these, a mention must be made of Polyphyto Dam, Greece, where the largest triggered earthquake of M 6.5 occurred on 13 May 1995 (Pavlou 2019), and Tranh River No.2, Vietnam, where the largest triggered earthquake was of M 4.6 on 22 October 2012 (Trieu et al. 2014).

Important Factors for RTS

Several studies examined the correspondence among possible correlates like rate of loading, highest water level reached and the duration of retention of high water levels, and the occurrence of RTS. The most important correlate is the depth of water column in the reservoir (Baecher and Keeney 1982). Figure 2 demonstrates that when the water column depth exceeds 150 m, about one in five reservoirs has experienced RTS. A review of recent global examples gives support to this observation. It must also be noted that a reservoir with a water volume exceeding 1 km³ and/or water depth exceeding 100 m is called a large reservoir. Globally there are more than one thousand such reservoirs, and only a small percentage has evidenced RTS.

Common Characteristics of RTS Sequences

By the early 1970s, over a dozen cases of RTS were known. In a couple of detailed studies, Gupta et al. (1972a, b) discovered several common characteristics of RTS sequences, which discriminated them from the normal earthquake sequences occurring in close by regions but not associated with reservoirs. These characteristics are:

1. In the earthquake frequency-magnitude relation ($\log N = A - bM$, where N is the number of earthquakes with magnitude $\geq M$ and A and b are constants), the foreshock

Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India, Fig. 2 Height of water column is the most important correlate (After Stuart-Alexander and Mark 1976)

and aftershock b values of the RTS sequences are higher than the b values for natural earthquake sequences in the regions concerned and the regional b values.

2. In addition to high b values, the magnitude ratio of the largest aftershock to the mainshock is also high.
3. Aftershock activity decays slowly compared to normal earthquake sequences.
4. The foreshock-aftershock sequence pattern belongs to Type II of Mogi's model (Mogi 1963), whereas the natural earthquake sequence pattern belongs to Type I of Mogi's model (Fig. 3 I).

The above mentioned observations are governed by the mechanical properties of the media, and their deviation from the normal implies changes in these properties consequent to impoundment of the artificial water reservoir. The sketch shown in Fig. 3 illustrates the changes. "A" in this figure is a homogeneous media rock volume. When the stress exceeds the strength

of the rock, there would be a major event releasing most of the strain, followed by peripheral adjustment aftershocks. In such an earthquake sequence, there would not be any foreshocks before the major event. The aftershock activity would be over in a short time, the ratio of the largest aftershock to the main event would be low, and the b value would also be low. This is typically the situation with the earthquake sequences in stable continental regions not associated with the reservoir loading. Due to filling of the water reservoir, the heterogeneity of the media increases ("B" in Fig. 3 II), and the rock volume gets fragmented. This results in the release of accumulated stresses by smaller rock volumes. In such a situation, the events would start occurring, as and when the strength of an individual rock volume is exceeded. The main event would correspond to the largest rock volume, and there would be events before it and after it, changing the pattern from Type I of Mogi's model to Type II. The ratio of the magnitude of the largest aftershock to the mainshock would also be high, and the b value of the foreshock sequence as well as the aftershock sequence would be high. This is what is observed with RTS sequences. These common characteristics were identified in the 1970s, based on around two dozen cases of RTS. Over the years, these are found to hold good for all cases of RTS investigated subsequently.

Mechanism of Triggered Earthquakes

In the following we give a gist of major milestones in comprehending the phenomenon of triggered earthquakes.

The foundation of understanding the phenomenon of triggered earthquakes was laid by the study of the waste fluid injection-induced earthquakes in the vicinity of the Rocky Mountain Arsenal well near Denver, Colorado, USA, in the early 1960s (Evans 1966). There are three main effects of reservoir loading relevant to triggering of earthquakes as pointed out by Gough and Gough (1970b) and several others:

1. The elastic stress increases following filling of the reservoir.
2. The increase in pore fluid pressure in saturated rocks, basically due to decrease in pore volume due to compaction, in response to increase in elastic stress.
3. Pore pressure changes related to fluid migration.

Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India, Fig. 3 (I) Depicts (Mogi 1963) classification of the earthquake sequences into three broad categories. (II) Cartoon for (A) homogenous rock mass and (B) fragmented rock mass. For details see the text

Gough and Gough (1970a, b) provided the first definitive quantitative analysis of the role of the load of the water reservoir in triggering earthquakes at Lake Kariba. The role of reservoir load in triggering earthquakes was also considered by Bell and Nur (1978) and Roeloffs (1988). They pointed out that reservoir-load-induced stresses at seismogenic depths are very small and can only perturb the ambient stress field. Gupta et al. (1972a, b) identified the rate of increase of reservoir water levels, maximum water levels reached, and the duration of retention of high water levels as factors affecting the frequency and magnitude of triggered earthquakes. The influence of pore fluid pressure in inducing earthquakes in very simple 1D reservoir models was presented by (Snow 1972). More sophisticated models were dealt by Withers and Nyland (1976), Bell and Nur (1978), and Roeloffs (1988) based on Biot's (1941) consolidation theory, which later on is generalized by Rice and Cleary (1976) by recognizing that the fluids too may be compressible. Very interesting results related to modeling of pore

pressure diffusion have been reported for Acu Reservoir in Brazil (Do Nascimento et al. 2004).

Pore pressure diffusion plays a very important role in the triggering of the earthquakes. However, there are a very few direct measurements of diffusivity, and it is mostly inferred from the temporal migration of seismicity. Talwani et al. (1999) have reported in situ measurements of hydrological diffusivity and Skempton's coefficient at the Bad Creek Reservoir in South Carolina, USA. At an observation well located 250 m away from the reservoir, a change in the water level of the well had a direct correspondence with the changes in the water level of the reservoir, initially with a delay of 98 h, which later stabilized at 72 h. This led to a frequency-independent estimate of diffusivity of $\sim 0.076 \text{ m}^2 \text{ s}^{-1}$ and Skempton's coefficient of 0.66 for an undrained response of the reservoir. Later, Talwani et al. (2007) analyzed more than 90 case histories of triggered seismicity and found diffusivity to vary between 0.1 and $10 \text{ m}^2 \text{ s}^{-1}$. This range of diffusivity values corresponds to a

range of intrinsic permeability between 5×10^{-16} and $5 \times 10^{-14} \text{ m}^2$. Talwani et al. (2007) referred to this range of the permeability of fractures as seismogenic permeability. Seismogenic permeability is an intrinsic property of fractures where pore pressure diffusion is associated with seismicity.

The in situ measurements of physical properties and examination of physical mechanism controlling triggered seismicity at Monticello Reservoir, South Carolina, USA, provided the much-needed field verification of the theoretical and model developments of the concept of triggered seismicity (Zoback and Hickman 1982). The effect of changes in lake levels and other derived parameters on triggered earthquakes have been dealt by Simpson and Negmatullaev (1981) for the Nurek Dam and by Gupta (1983) for the Koyna Dam. The part played by pore pressure diffusion in triggering earthquakes has been dealt by (Talwani and Acree 1984/1985). The effect of inhomogeneities in rock properties on triggering earthquakes was addressed by (Simpson and Narasimhan 1990).

Most of the theoretical models discussed the effect of pore fluid pressure in isotropic rocks. Chen and Nur (1992) point out that deviatoric effect of pore fluid pressure in anisotropic rocks has wide applications in comprehending triggered seismicity, earthquake precursors, and aftershocks. This approach needs to be applied to a few cases of RTS.

Other interesting studies include the notion of fault stability as a measure of the interplay of frictional stresses mobilized and the resolved shear stresses acting on a fault (Chander and Kalpna 1997). Kalpna and Chander (2000) have developed an algorithm for the simulation of stresses and pore pressure for more realistic laterally finite 3D models of reservoirs.

Koyna, India

Koyna reservoir located close to the west coast of India continues to be the most significant site of triggered earthquakes. Earthquakes began to occur soon after the impoundment of the Shivaji Sagar Lake created by the Koyna Dam in 1962. So far, globally the largest triggered earthquake of M 6.3 on 10 December 1967, 22 earthquakes of $M \geq 5$, about 200 earthquakes of $M \geq 4$, and several thousand smaller earthquakes have occurred in the region. Talking to the residents in the region in the 1960s revealed that they had not experienced any earthquake in the region in their living memory. There is a seismic station operating at Pune, about 120 km away from Koyna. A scrutiny of the seismograms revealed no earthquakes that could be assigned to the Koyna region. Another water reservoir, Warna, was impounded in 1985. This reservoir is located 35 km SSE of Koyna (Fig. 4). After the impoundment of Warna reservoir, the triggered activity got enhanced. For convenience, we shall call the Koyna and the Warna reservoir

region as the Koyna region. Major bursts of seismic activity associated with the Koyna reservoir occurred in 1967, 1993, 1980, 1993–1994, 2005, and 2009.

How Long Triggered Earthquakes Will Continue at Koyna?

Most RTS sites are located in stable continental regions (SCRs), where strain is of the order of 10^{-9} to 10^{-10} as compared to 10^{-5} at plate boundary and 10^{-7} to 10^{-9} for intraplate regions (Gupta and Johnston 1998). RTS typically gets initiated soon after the filling of the reservoir and may continue for a year to several years, with the largest event occurring within a few years of impoundment. The Hsingfengkiang Reservoir in China was impounded in 1959, and the largest RTS event of M 6.1 occurred on 19 March 1961. The frequency of RTS events dropped from thousands every month in the 1960s to a few every month by 1978 (Ishikawa and Oike 1982; Gupta 1992). Lake Kariba, located at Zambia-Zimbabwe border, was filled in 1958. The frequency of earthquakes increased several folds with the largest RTS event of M 6.2 occurring on 13 April 1963 (Gough and Gough 1970a, b). By 1974, RTS events dropped to less than 10% of 1963 level. At Kremasta, Greece, impoundment took place in 1965, and there was a very rapid filling of the reservoir in January 1966, and the largest RTS event of M 6.2 occurred on 5 February 1966 (Galanopoulos 1967; Stein et al. 1982). The RTS at Kremasta was short lived. However, at Koyna RTS was initiated in 1962 and has continued till now with the latest M 4 earthquake occurring on 20 June 2019. Gupta et al. (2002) have examined in detail the question as to how long the triggered earthquakes would continue at Koyna. The maximum credible earthquake for the Indian shield region has been estimated to be M 6.8. It is hypothesized that the region between Koyna and Warna was stressed close to critical before the impoundment of the Koyna reservoir and was capable of generating an M 6.8 earthquake. As demonstrated through the study of b values in earthquake magnitude-frequency relation, foreshock-aftershock patterns, the ratio of the magnitude of the largest aftershock to the mainshock, and the decay of aftershock activity in earthquake sequences at Koyna, the heterogeneity of the media has increased. None of the M~5 earthquake has occurred at the same location. M~5 earthquakes occur in Koyna region when the previous water maximum in the reservoir has been exceeded. Long time ago, Kaiser (1953) had reported that acoustic emission, under monotonically increasing stress, shows an appreciable increase after the applied stress exceeds the previously applied stress maxima. This approach has been successfully used by Yoshikawa and Mogi (1981) to estimate crustal stresses from cored samples. For the Nurek Dam also, it was reported that major triggered

Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India, Fig. 4 Updated from Gupta et al. (2017). Koyna-Warna region near west coast of India. Location of the Koyna main earthquake of 10 December 1967; earthquakes of $M \sim 5$ during August 1967 through June 2017; smaller earthquakes from August 2005 through June 2017; surface and borehole seismic

stations; green curve indicates the WGE (Western Ghat Escarpment). (I) Koyna location in India; (II) Distribution of $M \geq 3.7$ earthquakes for 1967–2015 (USGS) in the vicinity of Koyna and an outer circle of 100 km radius indicating that there is almost no seismic activity outside the Koyna region

events occurred when the water level in the reservoir reached the previous maximum and exceeded it (Simpson and Negmatullaev 1981). Gupta et al. (2002) had concluded that as of 2002, about one-half of an $M 6.8$ earthquake energy has been released in the Koyna region, and the activity should continue for another three to four decades. Due to the increase in heterogeneity, no fault segment, long enough to generate a $M > 6$ earthquake, is left intact, so an earthquake like the 10 December 1967 may not occur. The occurrence of $M \sim 5$ earthquakes would be governed by the fact whether the previous water maximum has been exceeded, and other factors such as the rate of loading, the highest water levels reached, and the duration of the retention of high water levels.

Short-Term Earthquake Forecast at Koyna

A case was made that short-term earthquake forecast may be feasible at Koyna (Gupta 2001). This was based on the fact that the shallow (depth ≤ 10 km) seismic activity in the vicinity of the Koyna is confined to an area of 20×30 km², and there is no other seismic source within 50 km radius. Every year, following the rainy season, the reservoirs get filled, and there is an enhancement of seismic activity. From among earthquake precursors, foreshocks are important and have a potential in forecasting earthquakes (Dodge et al. 1996; Helmstetter et al. 2003). Ohnaka (1992) has noted that immediate foreshock activity is a part of the nucleation process leading to mainshock

Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India, Table 2 Events preceding $M \geq 4.0$ earthquakes in Koyna region

Main earthquake	Duration of nucleation period (hours)	No. of events before the main earthquake				
		<i>M</i> 1.0–1.9	<i>M</i> 2.0–2.9	<i>M</i> 3.0–3.9	Largest earthquake	50 h prior to the beginning of nucleation period
30 August 2005 M 4.8	110	13	8	0	2.6	2
13 November 2005 M 4.0	160	18	8	1	3.0	3
26 December 2005 M 4.2	150	22	8	0	2.9	6
17 April 2006 M 4.7	380	40	10	0	2.7	2

dynamic rupture. Gupta et al. (2007) have reported successful earthquake forecast in Koyna based on identification of nucleation in real time. The seismic activity in the Koyna region is monitored by a closely spaced network of seven modern seismic stations. Table 2 from Gupta et al. (2007) is the learning phase where four earthquakes of $M 4.0$ to $M 4.8$ were found to be preceded by well-defined nucleation where several events occurred in a tight cluster of less than 10 km radius (Fig. 5a–d). It was realized that if the formation of nucleation could be identified in real time before the occurrence of the mainshock, it may be possible to make a short-time forecast.

During the middle of May 2006, an interesting situation was developed. The events in the Koyna region for the period 11–16 May 2006 are depicted in Fig. 6a (Gupta et al. 2007). By the afternoon of 16 May 2006, some 50 events of $M \geq 1.0$, the largest being $M 2.7$, had occurred in the preceding 107 h in a small area, the focal depth being between 2 and 8 km. It was inferred that the region is going through a nucleation phase. Based on the experience of previous nucleation, the following forecast was made at 19:05 IST and communicated to the Editor of *Current Science*, Secretary of the Ministry of Earth Sciences of the Government of India, and the President of the Geological Society of India: “On the basis of the data available from seven seismic stations operating in the Koyna region, we have identified a nucleation which started on 12 May 2006. This may lead to the occurrence of an $M \sim 4$ earthquake in the next 15 days. This shallow earthquake (focal depth less than 8 km) will occur within a radius of 10 km centered at 17.1°N , 73.8°E . On the basis of our previous experience of studying nucleation-preceding earthquakes in the Koyna region, we expect this earthquake to occur over the next 15 days time (till 31 May 2006), with a 50% probability.” An earthquake of $M 4.2$ occurred on 21 May. Table 3 gives the comparison of forecasted parameters and that of 21 May 2006 earthquake. Since 2006, eight similar short-term forecasts have been made in the Koyna region, and all have come true.

Near-Source Studies at Koyna

The correspondence between the water level variations in Koyna and Warna reservoirs and observed RTS is well established. However, in the absence of the knowledge of physical properties of rocks and fluids in the fault zone, the triggering mechanism is not comprehended. This necessitates near-source studies of earthquakes in the Koyna region. The fact that the RTS is confined to a small area of 30×20 km, most of the earthquakes occur within a depth of 2–9 km; there is no other source of earthquakes within 100 km of Koyna Dam, and the region is easily accessible for all kind of field observations, and temperatures are estimated to be $\sim 130^\circ\text{C}$ at a depth of 6 km, making Koyna an ideal site for setting up of a deep borehole laboratory. The project of setting up of a borehole laboratory for near-field study of earthquakes was discussed in an International Continental Drilling Program (ICDP) sponsored discussion meeting during 21–26 March 2011, where global experts participated and supported the proposed program and suggested certain field work and observations to be carried out before putting the borehole (Gupta and Nayak 2011). In the following 3 years, the recommended investigations were carried out. These included (1) drilling of nine boreholes into the basalt column and penetrating the granitic basement to a depth of 300–500 m, (2) airborne gravity gradient and magnetic surveys covering the entire RTS area, (3) magnetotelluric surveys to map the subsurface and estimate the thickness of basalt cover, (4) LiDAR surveys for getting a bare-earth model and getting a high-resolution topography, (5) instrumenting of six boreholes with three component seismometers for better estimate of the focal parameters of the earthquakes, and (6) heat flow measurements to estimate temperatures at depths of 6 km. The work carried out during 2011–2014 was reported in the 2nd ICDP workshop held during 16–18 May 2014 at Koyna and Karad (Gupta et al. 2014). The results were also presented elsewhere (Gupta et al.

Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India, Fig. 5 Seismic activity for the period 50 h before the start of nucleation till the occurrence of $M \geq 4$ earthquakes in Koyna region during August 2005–April 2006. Foreshocks clustering before the mainshocks in a region of 10 km radius (right). Temporal distribution of events within the circle with the depth. $\circ$, $\circ$, $\diamond$, $\star$

and $\star$ are events in M 1.0–1.9, 2.0–2.9, and 3.0–3.9 ranges and main earthquake, respectively (left). The onset of identified nucleation period is given "0" time mark. Nucleation period lasted for 110, 160, 150, and 380 h for (a) 30 August, (b) 13 November, and (c) 26 December 2005 and (d) 17 April 2006 earthquakes, respectively (Table 2)

Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India, Fig. 6 Symbols as in Fig. 5. (a) Events that occurred during 107 h (11–16 May) preceding the identification of nucleation. (c) Temporal-depth plot of the events within the 10-km-

radius circle. Nucleation was inferred to have started 107 h before, where 0 h is put on the time axis. (b) Seismic activity from 13:35 UTC on 16 May till the occurrence of the M 4.2 earthquake on 21 May 2006, on the right side of (c)

2016; Gupta 2017, 2018). Many of the 2nd ICDP workshop participants had participated in the 1st ICDP workshop as well. Satisfied with the progress made, a go ahead was given to put a 3-km-deep Pilot Borehole.

Pilot Borehole Location

Five possible locations were examined for suitability of placing the Pilot Borehole (Gupta et al. 2017). Finally, based on

Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India, Table 3 Forecast of 21 May 2006 M 4.2 earthquake in Koyna on 16 May 2006

	Forecast parameters	Occurrence
Epicenter	Within 10 km radius of 17.1° N, 73.8° E	17.171° N, 73.777° E
Magnitude	~ 4	4.2
Time	Within 15 days of 16 May 2006, i.e., until 31 May 2006	20:29:01 UTC On 21 May 2006
Focal depth	Less than 8 km	4.7 km

vicinity of site D (Fig. 7) to the Donachiwada fault, which hosted the 10 December 1967 M 6.3 earthquakes and many other events of $M > 4$, logistic convenience, and the trend of earthquakes for the period 2005–2015, it was chosen to place the Pilot Borehole. Drilling of the Pilot Borehole started on 20 December 2016, and the borehole was completed on 11 June 2017. Granitic basement was reached at a depth of 1247 m. No sediments were found below the basalt. Zones of huge fluid losses were encountered at several depths. An online gas analysis facility has been set up. Measurements of *in situ* stresses were made at depths of 1600 m and deeper. It is found that 10^{-16} to 10^{-14} permeability of the granites would not produce significant pore fluid pressure changes to trigger earthquakes. However, core samples of granites at 1522 m depth provided evidence of fractured zones that would contribute to water channelization and triggering of earthquakes (Hazarika et al. 2017). Measurement of elastic properties of granitoids from Koyna region showed low and variable rock strength compared with granitic rocks of aseismic areas (Goswami et al. 2017). The 3rd ICDP post-operation workshop was held during 14 to 16 October 2017 to

review the work carried out to develop plans for the Main Borehole of ~ 6 km depth, its instrumentation, and future course of action (Podugu et al. 2018). In a recent study, detailed geophysical logging revealed seven anomalous zones below 2100 m depth (Goswami et al. 2019), characterized by shear wave velocity anomaly of up to 25%. All the data acquired are being analyzed for finalizing the specifications of the proposed ~ 6 km deep Main Borehole.

Summary

In this article we provide a thumbnail review of studies of global occurrence of artificial water reservoir-triggered earthquakes, with a special emphasis on Koyna, India. Considering the small changes in the stress regime caused by filling of the deepest reservoirs compared to the stress drop of the associated earthquakes, it is appropriate to replace “reservoir-induced seismicity” by “reservoir-triggered seismicity.”

Koyna continues to be the most significant sight of RTS globally. The latest M 4 earthquake occurred on 20 June 2019.

Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India, Fig. 7 (a) Earthquakes of $M \geq 2.0$ in the vicinity of block D during August 2005–December 2015. A 2-km swath is indicated by dotted lines. The surface expression of the Donachiwada fault is indicated by dashed lines. (b) Depth section of hypocenters for the period 2005–2015 for the 2-km-wide swath. (c) Earthquakes in the 2-km swath for the period 2016–2017

At Koyna, earthquakes of M 4–5 are often preceded by well-defined clusters of foreshocks of $M \leq 3$, referred as nucleation that is found to last typically 100–400 h. Identification of nucleation in real time has led to successful short-term forecasts of $M \sim 4$ earthquakes.

The study of RTS provides exceptionally good opportunity to comprehend physics of earthquakes, finding safer sites of creating artificial water reservoirs and bringing us closer to accurate short-term earthquake forecasts.

Setting up of a deep borehole laboratory for near-field study of earthquakes is underway at Koyna. The first phase of setting up of a 3-km-deep Pilot Borehole has been successfully completed. One of the major discoveries has been that it is not the fluid flow through permeability, but through deep fractures discovered at depths of 3 km in the seismic zone that trigger earthquakes.

Definition

Biogeophysics Subdiscipline of exploration geophysics focusing on the geophysical signatures resulting from microbial communities and their interactions with geologic media.

Introduction

Geophysical imaging techniques have the potential to measure not just the subsurface physical and chemical properties, as geophysics is conventionally used, but also microbes, microbial processes, and microbe-mineral interactions. “Biogeophysics” is defined here as a rapidly evolving discipline of exploration geophysics concerned with the geophysical signatures of microbial communities and their interactions with geologic media that combines the fields of microbiology, biogeoscience, and geophysics (Atekwana and Slater 2009) (Fig. 1). Within this context, biogeophysics examines the links between dynamic subsurface microbial processes, microbial-induced alterations to geologic materials, and geophysical signatures. We note that the term biogeophysics is also used in other disciplines (a) to describe research into the origins of life and (b) to describe fluxes of energy, water, and momentum between earth surface and the atmosphere. Our use of the term describes how it has been adopted by the exploration geophysics community in recognition of the geophysical signatures of microbial activity.

These geophysical signatures may arise from (1) microbial cells and extracellular structures themselves, (2) growth of microorganisms (production of biomass) and biofilm formation, (3) generation of metabolic by-products and the interactions of these metabolites with the host material, and (4) microbially mediated processes. The geophysical signatures arising from each of these four source mechanisms are described below.

Geophysical Detection of Cells and Biofilms

Microbial cells and biofilms exhibit distinct electrical properties and certain (magnetotactic) bacteria also display unique magnetic characteristics. The membrane potential (the voltage drop across the membrane due to the negatively charged molecules inside cells) of live cells results in an accumulation of mobile electric charge carriers at membrane surfaces. When live cells are placed in time-oscillating electric fields, these charges move on the surface of the membrane, giving rise to high polarizations for cellular suspensions that are readily measured with dielectric spectroscopy. As the mobility of these surface charges is relatively small, this effect is manifest at low frequencies, such that the relative dielectric permittivity of live cell suspensions can be as high as 10^6 (Prodan et al. 2004; Stoy et al. 1982). The outer and inner cell radii, diffusion constants, and membrane potential all have a very distinct effect on broadband dielectric spectroscopy data (Prodan et al. 2008). Polarization enhancement is also observed when microbial cells are present in high concentrations in porous media (Ntarlagiannis et al. 2005). This polarization signature of porous media has been modeled in terms of the growth curve for microbial populations (Revil et al. 2012; Mellage et al. 2018). The mechanism may be enhanced when cells are more preferentially adsorbed onto mineral surfaces (Abdel Aal et al. 2009).

The magnetic properties of soils and rock are altered by a diverse group of prokaryotes that exert a significant control over magnetite formation in two ways that differ mechanistically: biologically induced mineralization (BIM) and

Biogeophysics, Fig. 1 Primary disciplinary themes encompassing biogeophysics

biologically controlled mineralization (BCM) (Jimenez-Lopez et al. 2010). Biologically induced magnetite formation is indistinguishable from magnetite formed by inorganic processes; however, biologically controlled magnetite formation is distinct and produced by magnetotactic bacteria (Jimenez-Lopez et al. 2010). These magnetotactic bacteria biomineralize intracellular, membrane-bound, single-magnetic-domain crystals of the magnetic minerals magnetite and/or greigite called magnetosomes (Bazylnski and Frankel 2004). Magnetotactic bacteria are typically found in a wide variety of aquatic environments (e.g., fresh water lakes) with the highest numbers occurring mostly at oxic-anoxic interfaces. The presence of magnetotactic bacteria in sediments is often used as a proxy for paleoenvironmental/climatic conditions, and the presence of magnetosomes in sediments and other secondary magnetic minerals produced by microbial activity likely impacts the magnetic properties of the subsurface recorded with magnetic geophysical techniques as has been demonstrated at hydrocarbon contaminated sites (Rijal et al. 2010).

Biofilms (an attached state of cell growth, whereby cells are closely packed and firmly attached to each other) further alter the geophysical properties of soils. Low frequency electrical measurements respond to self-limiting microbial growth/cell attachment and biofilm formation in porous media, as well as death and lyses of cells (Davis et al. 2006). Electrical polarization may result from the electrical properties of the biofilm itself or from the modification of grain surfaces due to cell attachment. Biofilms also alter the

acoustic properties of porous media, with biofilm growth in soil columns resulting in spatial complexity of acoustic amplitudes (Davis et al. 2009). Such variations likely arise from a nonuniform distribution of microbial activity or heterogeneity in the biomass distribution and biofilm morphology (e.g., variations in biofilm thickness, roughness, hydration, etc.).

Geophysical Detection of Metabolic By-Products and Mineral Weathering

Microbial metabolism enhances the weathering of minerals through the attachment, growth, and colonization of mineral surfaces by microorganisms (Bennett et al. 1996). Metabolic by-products, including biogenic gases (e.g., CO_2 , H_2S , CH_4 , etc.), organic acids, and biosurfactants all affect electrical properties of porous media. Microbial production of organic acids and biosurfactants adds ions to solution, increasing electrolyte concentration of pore fluids (Cassidy et al. 2001). Organic acids enhance mobility of sparingly soluble metals and also increase the number of reaction sites, thus accelerating mineral weathering (Hiebert and Bennett 1992). Enhanced mineral dissolution catalyzed by increased organic acid concentration can lead to physical changes in grain surface morphology, surface area, surface roughness, and the generation of secondary porosity and increased permeability (McMahon et al. 1992). These changes in porosity affect acoustic wave propagation by altering grain contact coupling and changes in surface area/roughness drive changes in electrical polarization. Biogenic gases reduce bulk electrical conductivity and enhance attenuation of seismic signal amplitudes.

The effects of metabolic by-products on geophysical properties have been recorded in hydrocarbon-contaminated environments (Abdel Aal et al. 2004; Werkema et al. 2003). Such sites are natural bioreactors where excess organic substrates stimulate microbial activity. Enhanced mineral weathering in hydrocarbon-contaminated aquifers (Hiebert and Bennett 1992; McMahon et al. 1995) increases pore fluid conductivity and thereby bulk conductivity sensed with a range of electromagnetic methods (Abdel Aal et al. 2004; Atekwana et al. 2004; Sauck et al. 1998). Elevated bulk conductivity is therefore found where intrinsic bioremediation and enhanced mineral weathering are occurring. These zones of highest bulk electrical conductivity may coincide with the highest percentages of oil-degrading microbial populations, with spatial heterogeneity in the microbial community structure and shifts in the microbial community concomitant with vertical changes in bulk electrical conductivity (Allen et al. 2007). Biogenic methane production by archaea in anaerobic soils can result in extensive free phase gas production that reduces dielectric permittivity and electrical conductivity (Comas and Slater 2007; Parsekian et al. 2010).

Geophysical Detection of Microbially Mediated Redox Processes

Microbial metabolic activity is a critical driver of redox chemistry because microbes derive energy from oxidation-reduction reactions (the transfer of electrons from one reactant to the other). Terminal electron acceptors (TEAs) govern nutrient utilization by microbes during the breakdown of organic carbon (Cozzarelli et al. 1999). Microbial respiration consequently results in reduced conditions and strong redox gradients in the Earth typically develop in the presence of heterotrophic bacteria. Significant changes in Eh and pH result in new mineral stability fields in which some minerals become unstable and are dissolved and mobilized, whereas others may precipitate from solution. As TEAs are consumed, changes in pore fluid chemistry may drive changes in pore fluid conductivity, thereby affecting bulk electrical conductivity.

Strong electrical potentials associated with current sources in the Earth are correlated with redox gradients recorded at sites where microbial degradation of hydrocarbons is occurring (Minsley et al. 2007; Naudet et al. 2003). Such large potentials require geobatteries traditionally invoked to explain very large (~1.0 V) potential gradients due to internal current sources recorded over electronically conductive ore bodies straddling the large redox gradient provided by the water table (Sato and Mooney 1960). Biogeobatteries may occur in conjunction with a strong redox gradient between highly reducing conditions below the water table within a contaminant plume and an oxidized zone above the water table if microbial activity can generate the required electron bridge (Revil et al. 2010; Heenan et al. 2017). Possible mechanisms facilitating electron migration include iron oxides, clays, and conductive biological materials (Revil et al. 2010). Metal-reducing organisms, such as *Shewanella* and *Geobacter*, produce electrically conductive appendages called bacterial nanowires that may facilitate electron transfer to solid phase electron acceptors (Reguera et al. 2005). However, the ability of biofilms to facilitate electron transport over the scale of the groundwater interface is unknown although new evidence suggests that such electron transfer can take place at mm scales (Nielsen et al. 2010). Nonetheless, more studies are needed to confirm this finding.

Geophysical Detection of Microbe-Mineral Transformations

Biogeochemical processes result in mineral precipitation that alters the physicochemical properties of the grain surfaces. When microbial-induced precipitation is extensive,

the volumetric physical properties of porous media are modified. In anaerobic environments, iron-reducing bacteria and sulfate-reducing bacteria can use Fe(III) and sulfate, respectively, as terminal electron acceptors. Ferrous iron produced by iron-reducing bacteria promotes the precipitation of electrically conductive secondary minerals such as siderite (FeCO_3), magnetite (Fe_3O_4), and goethite (FeOOH) (Fredrickson et al. 1998). Magnetic susceptibility is a simple and powerful geophysical parameter for monitoring iron mineral transformations coupled to microbial induced oxidation of hydrocarbons (Atekwana et al. 2014; Lund et al. 2017). Sulfide produced during microbial sulfate reduction can react with iron (II) produced by iron-reducing bacteria to precipitate iron sulfide minerals. Strong seismic and electrical signatures are generated as a result of microbe-induced ZnS and FeS precipitation (Williams et al. 2005). Decreases in seismic wave amplitude result from the development of differential elastic moduli associated with accumulation of metal sulfide-encrusted microbes within pores (Williams et al. 2005). Electrical signals result from the formation, movement, and dissolution of electronically conductive biominerals that profoundly enhance the polarization of a porous medium. These electrical signals may be diagnostic of both the concentration and the distribution of the biominerals throughout a porous medium (Slater et al. 2007).

Geophysical signals also result when microbial processes involve the precipitation of semimetallic or nonmetallic minerals, e.g., metabolically induced calcite precipitation by bacterial hydrolysis of urea (Ferris et al. 1995). Relative to metallic minerals, smaller electrical signals result from changes in pore volume/pore tortuosity and/or surface area/surface roughness driven by precipitation of nonmetallic minerals (Wu et al. 2010). Calcite precipitation induced by bacteria has been shown to form cements in porous media and affect subsurface fluid flow (Ferris et al. 1995). Such cements profoundly change the elastic properties of soils and rocks, particularly when ureolysis is stimulated to form calcite cement that acts to stiffen the soil matrix (DeJong et al. 2006). Shear waves are well suited to monitoring changes in the particle soil matrix due to precipitation as shear velocity (V_s) is largely unaffected by pore fluid composition and directly dependent on void ratio, coordination number (average number of surrounding particles a given particle is in contact with), and confining stress (DeJong et al. 2010). Large changes in shear wave velocity accompany stiffening result from initial binding of microbes to the soil matrix, suggesting that relatively small volumes of precipitates can generate large geophysical signals. Electrical signals can also be used to monitor soil strengthening by microbial precipitation of calcite (Saneiyan et al. 2019).

Summary

Twenty years ago, it seemed inconceivable to suggest that microbial processes could potentially impact geophysical signatures. However, today it is clear that geophysical signatures result from a range of microbial processes covering the scale of an individual cell to the scale of contaminant plumes in the Earth. A pressing question in biogeophysics remains how to better quantify the geophysical signatures of microbial processes through the development of appropriate modeling frameworks. Success in this venture will require new multidisciplinary research between geophysicists, biogeochemists, and microbiologists.

Body Waves

Mahmoud Mohamed Selim Saleh

Department of Nature and Applied Sciences, Al-Aflaj Community College, AL-Kharj University, Al-Aflaj, Riyadh, Saudi Arabia

Synonyms

Energy waves generated by an earthquake or an artificial explosion

Definition

Waves consist of a disturbance in materials (media) that carries energy and propagates. However, the material that the wave propagates in generally does not move with the wave. The movement of the material is generally confined to small motions, called particle motion, of the material as the wave passes. After the wave has passed, the material usually looks just like it did before the wave, and, is in the same location as before the wave. When stress builds up in the Earth to such a level that rapid slip occurs on a fracture (i.e., an earthquake takes place) or when an explosion or mechanical device is used to initiate a seismic disturbance artificially, a complex field of seismic waves is generated. This wave field propagates much like the waves that travel away from the point at which a stone is thrown into a pond. Waves that travel through the interior of the Earth are called body waves. They follow ray paths bent by the varying density and modulus (stiffness) of the Earth's interior. The density and modulus, in turn, vary according to temperature, composition, and phase. These waves are usually observed at higher frequency.

Types of Body Waves

There are two main kinds of body waves: P-waves and S-waves, so-named because they are the primary and secondary waves detected by a seismograph (Fig. 1). The P-wave is always the first wave to arrive at a seismometer, closely followed by its reflection from the surface and S-waves arrive next. P-waves, or compressional waves, are longitudinal waves (wave motion in the direction the wave is traveling). S-waves are transverse waves or shear waves, involving a back-and-forth shearing motion at right angles to the direction the wave is traveling (Fig. 2). Body waves are reflected and transmitted at interfaces where the seismic velocity and/or density changes, obeying Snell's Law. At such an interface,

Body Waves, Fig. 1 P- and S-wave recorded in a three-component seismograph.

Body Waves, Fig. 2 P- and S-waves motion. The arrow shows the direction that the wave is moving

or discontinuity, some of the energy of an incident body wave is reflected as a P-wave, some as an S-wave, some is transmitted as a P-wave and some as an S-wave. The notation for the various seismic ray paths within the Earth are as follows:

When an earthquake occurs, seismic waves are emitted from the focus (hypocenter); there are several paths that it can take through the Earth before emerging again at the surface. These paths (refer to Fig. 3) are symbolized by the letters: p = P-wave arrival from a path that traveled upward from the focus (hypocenter); pP = P-wave arrival from a path that traveled upward from the focus, reflected off the surface of the Earth, then arrived back at the surface; P = P-wave arrival from a path that traveled downward from the focus (hypocenter); PP = P-wave reflected off the surface once; PPP = P-wave reflected off the surface twice; c = a reflection off the outside of the outer surface of the outer core – note that this is the principle cause of multiple arrivals of P- and S-waves right at the epicenter; K = a travel path (refraction) through the outer core; KK = one reflection on the inside outer surface of the outer core; KKK = two reflections off the inside outer surface of the outer core; i = a reflection off the outside of the outer surface of the inner core; I = a travel path (refraction) through the inner core. These letters can be used to indicate the path of a seismic wave through the Earth (Fig. 3). For example PKiKP indicates that the wave traveled downward from the focus, refracted through the outer core, reflected off the surface of the inner core, traveled through the outer core, and then traveled through the mantle to arrive at the surface. SKiKS is the same path, but an S-wave. Because liquids have no resistance to shear and cannot sustain a shear wave, S-waves cannot travel through liquid material. The Earth's outer core is

believed to be liquid because S-waves disappear at the mantle–core boundary, while P-waves do not.

Wave Propagation

Seismic body waves propagate through the Earth's interior. Because of the elastic properties of the Earth's materials (rocks) and the presence of the Earth's surface, four main types of seismic waves propagate within the Earth. Compressional (P) and Shear (S) waves propagate through the Earth's interior.

Waves on a Seismogram

If we look at a seismogram, we expect to see the first wave to arrive to be a P-wave (the fastest), then the S-wave, and finally, the Love and Rayleigh (the slowest) waves. As you might expect, the difference in wave speed has a profound influence on the nature of seismograms. Since the travel time of a wave is equal to the distance the wave has traveled divided by the average speed the wave moved during the transit, we expect that the fastest waves arrive at a seismometer first. The fact that the waves travel at speeds that depend on the material properties (elastic moduli and density) allows us to use seismic-wave observations to investigate the interior structure of the planet. We can look at the travel times, or the travel times and the amplitudes of waves to infer the existence of features within the planet, and this is an active area of seismological research. To understand how we “see” into Earth using vibrations, we must study how waves interact with the rocks that make up Earth. Several types of interaction between waves and the subsurface geology (i.e., the rocks) are commonly observable on seismograms. We will examine the two simplest types of interaction, refraction and reflection.

Refraction

As a wave travels through Earth, the path it takes depends on the velocity. Perhaps you recall from high school a principle called Snell's law, which is the mathematical expression that allows us to determine the path a wave takes as it is transmitted from one rock layer into another. Snell's law describes the relationship between the angles and the velocities of the waves. Snell's law equates the ratio of material velocities V_1 and V_2 to the ratio of the sines of incident (θ_1) and refracted (θ_2) angles, as shown in the following equation:

$$\frac{\sin \theta_1}{V_{L_1}} = \frac{\sin \theta_2}{V_{L_2}} \quad (1)$$

where V_{L_1} is the longitudinal wave velocity in material 1 and V_{L_2} is the longitudinal wave velocity in material 2.

Note that in Fig. 4, there is a reflected longitudinal wave ($V_{L'}$) shown. This wave is reflected at the same angle as the incident wave because the two waves are traveling in the same

Body Waves, Fig. 3 P- and S-wave paths in the Earth's interior

Body Waves, Fig. 4 Reflected ($V_{L1'}$) and refracted (V_{L2}) longitudinal waves

material, and hence have the same velocities. This reflected wave is unimportant in our explanation of Snell's law, but it should be remembered that some of the wave energy is reflected at the interface. When a longitudinal wave moves from a slower to a faster material, there is an incident angle that makes the angle of refraction for the wave 90° . This is known as the first critical angle. The change in direction depends on the ratio of the wave velocities of the two different rocks. When waves reach a boundary between different rock types, part of the energy is transmitted across the boundary. The actual interaction between a seismic wave and a contrast in rock properties is more complicated because an incident P-wave generates transmitted and reflected P- and S-waves and also an incident S-wave generates transmitted and reflected P- and S-waves, so five waves are involved. The transmitted wave travels in a different direction, which depends on the ratio of velocities of the two rock types (Figs. 5 and 6). Part of the energy is also reflected backwards into the region with rock type 1, but we have not shown that on these figures. Refraction has an important effect on waves that travel through Earth. In general, the seismic velocity in Earth increases with depth (there are some important exceptions to this trend) and refraction of waves causes the path followed by body waves to curve upward (Fig. 7).

Reflection

The second wave interaction with variations in rock type is reflection. I am sure you are familiar with reflected sound waves: we call them echoes. And your reflection in a mirror or pool of water is composed of reflected light waves. In seismology, reflections are used to prospect for petroleum and investigate Earth's internal structure. In some instances, reflections from the boundary between the mantle and crust may induce strong shaking that causes damage about 100 km from an earthquake (we call that boundary the "Moho" in honor of Mohorovicic, the scientist who discovered it). A seismic reflection occurs when a wave impinges on a change in rock type (which usually is accompanied by a change in seismic-wave speed). A part of the energy carried

Body Waves, Fig. 5 Velocity in rock type 2 is greater than velocity in rock type 1

Body Waves, Fig. 6 Velocity in rock type 2 is less than velocity in rock type 1

Body Waves, Fig. 7 The overall increase in seismic-wave speed with depth in the Earth produces an upward curvature to rays that pass through the mantle. A notable exception is caused by the decrease in velocity from the mantle to the core. This speed decrease bends waves backwards and creates a "P-wave shadow zone" between about 100° and 140° distance ($1^\circ = 111.19$ km)

by the incident wave is transmitted through the material (that is the refracted wave described above), and a part is reflected back into the medium that contained the incident wave (Fig. 8). The amplitude of the reflection depends strongly on the angle that the incident wave makes with the boundary and the contrast in material properties across the boundary. For some angles, all the energy can be returned into the medium containing the incident wave. An incident P-wave generates transmitted and reflected P- and S-waves and so five waves are involved. Likewise, when an S-wave interacts with a boundary in rock properties, it too generates reflected and refracted P- and S-waves. Because major boundaries between different rock types within the Earth are normally

Body Waves, Fig. 8 When a wave encounters a change in material properties (seismic velocities and or density), its energy is split into reflected and refracted waves

approximately parallel to the Earth's surface, S-wave particle motion is commonly in the SV (perpendicular to the ray path and vertical) and SH (perpendicular to the ray path and horizontal) directions. P-waves travel faster than S-waves, so there will be separate wave front representations for the P- and S-waves (Fig. 9). If the physical properties of the material through which the waves are propagating are constant, the wave fronts will be circular (or spherical in three dimensions). If the physical properties vary in the model, the wave fronts will be of more complex shapes. In the transverse or shear wave, the particles oscillate at a right angle or transverse to the direction of propagation. Shear waves require an acoustically solid material for effective propagation, and therefore, are not effectively propagated in materials such as liquids or gases. Shear waves are relatively weak when compared to longitudinal waves. In fact, shear waves are usually generated in materials using some of the energy from longitudinal waves.

Velocity

Among the properties of waves propagating in isotropic solid materials are wavelength, frequency, and velocity. The wavelength (λ) is directly proportional to the velocity of the wave (C) and inversely proportional to the frequency (f) of the wave. The phase velocity of a seismic wave can be written as:

$$C = \omega/k, \quad (2)$$

where $\omega = 2\pi f$ is the angular frequency and $k = \lambda/2\pi$ is wave number.

Velocity of P- and S-waves

Seismic waves travel fast, of the order of kilometers per second (km/s). The precise speed that a seismic wave travels depends on several factors, the most important of which is the composition of the rock. We are fortunate that

Body Waves, Fig. 9 Wave fronts and ray paths in seismic-wave propagation

the speed depends on the rock type because it allows us to use observations recorded on seismograms to infer the composition or a range of compositions of the planet. But the process is not always simple, because sometimes different rock types have the same seismic-wave velocity, and other factors also affect the speed, particularly temperature and pressure. Temperature tends to lower the speed of seismic waves and pressure tends to increase the speed. Pressure increases with depth in Earth because the weight of the rocks above increases with increasing depth. Usually, the effect of pressure is larger and in regions of uniform composition, the velocity generally increases with depth, despite the fact that the increase of temperature with depth works to lower the wave velocity. When the different seismic-wave types are described below, I will quote ranges of speed to indicate the range of values we observe in common terrestrial rocks. But you should keep in mind that the specific speed throughout Earth will depend on composition, temperature, and pressure.

P-waves

P-waves are the first waves to arrive on a complete record of ground shaking because they travel the fastest (their name derives from this fact—P is an abbreviation for primary, first wave to arrive). They typically travel at speeds between ~ 1 and ~ 14 km/s. The slower values correspond to a P-wave traveling in water, the higher number represents the P-wave speed near the base of Earth's mantle. The velocity of a wave depends on the elastic properties and density of a material. If we let κ represent the bulk modulus of a material, μ the shear modulus, and ρ the density, then the P-wave velocity, which we represent by C_P , is defined by:

$$C_P = \sqrt{\frac{\lambda + 2\mu}{\rho}} \quad (3)$$

A modulus is a measure of how easy or difficult it is to deform a material. For example, the bulk modulus is a measure of how a material changes volume when pressure is applied and is a characteristic of a material. For example, foam rubber has a lower bulk modulus than steel. P-waves are sound waves, it is just that in seismology we are interested in frequencies that are lower than humans' range of hearing (the speed of sound in air is about 0.3 km/s). The vibration caused by P-waves is a volume change, alternating from compression to expansion in the direction that the wave is traveling. P-waves travel through all types of media – solid, liquid, or gas.

S-waves

Secondary, or S-waves, travel slower than P-waves and are also called “shear” waves because they do not change the volume of the material through which they propagate – they shear it. S-waves are transverse waves because they vibrate the ground in a direction “transverse,” or perpendicular, to the direction that the wave is traveling.

The S-wave speed, call it C_S , depends on the shear modulus and the density

$$C_S = \sqrt{\frac{\mu}{\rho}} \quad (4)$$

Even though they are slower than P-waves, the S-waves move quickly. Typical S-wave propagation speeds are of the order of 1–8 km/s. The lower value corresponds to the wave speed in loose, unconsolidated sediment, the higher value is near the base of Earth's mantle. An important distinguishing characteristic of an S-wave is its inability to propagate through a fluid or a gas because fluids and gases cannot transmit shear stress and S-waves are waves that shear the material. The velocity of seismic waves depends on the elastic properties and density of a material in which the wave is traveling. P-waves are sound waves, it is just that in seismology we are interested in frequencies that are lower than humans' range of hearing (the speed of sound in air is about 0.3 km/s). The vibration caused by P-waves is a volume change, alternating from compression to expansion in the direction that the wave is traveling. In general, earthquakes generate larger shear waves than compressional waves and much of the damage close to an earthquake is the result of strong shaking caused by shear waves.

Attenuation

Near the source of a strong disturbance, such as a large explosion or earthquake, the wave-generated deformation can be large enough to cause permanent deformation, which

Body Waves, Fig. 10 Amplitude spectrum in red is for signal after attenuation

will be visible as cracks, fault offsets, and displacements of the ground after the disturbance has passed. A source of energy creates the initial disturbance and the resulting waves propagate (travel) outward from the disturbance. Because there is finite energy in a confined or short-duration disturbance, the waves generated by such a source will spread out during propagation and become smaller (attenuate) with distance away from the source or with time after the initial source, and thus, will eventually die out (Fig. 10). Knowledge of attenuation can be very useful in seismic data processing, as its removal increases resolution.

Attenuation often serves as a measurement tool that leads to the formation of theories to explain physical or chemical phenomenon that decreases the body wave's intensity. The amplitude change of a decaying plane wave can be expressed as:

$$A = A_0 e^{-\alpha z} \quad (5)$$

In this expression, A_0 is the unattenuated amplitude of the propagating wave at some location. The amplitude A is the reduced amplitude after the wave has traveled a distance z from the source. The quantity α is the attenuation coefficient of the wave traveling in the z -direction. The more common unit of the attenuation value is Decibels. Attenuation is generally proportional to the square of the frequency. Quoted values of attenuation are often given for a single frequency, or an attenuation value averaged over many frequencies may be given. The quoted values of attenuation only give a rough indication of the attenuation and should not be automatically trusted. Generally, a reliable value of attenuation can only be obtained by determining the attenuation experimentally for the particular material being used.

Summary: Results of Regional and Global Studies

The study of seismic body waves permits us to derive important knowledge about the internal constitution of the Earth.

The problems related to propagation of elastic seismic body waves has been discussed in a number of books and in numerous papers (e.g., Bromwich 1898; Sezawa 1927; Haskell 1953; Ewing et al. 1957; Brekhovskikh 1960; Bullen 1963; Bath 1968; Achenbach 1975 and others). Attenuations of seismic waves have been investigated by many authors (e.g., McDonald et al. 1958; Knopoff and Macdonald 1958; Kolsky 1963; White 1965; Kuster and Toksoz 1974; Shoenberger and Levin 1974; Kennett 1983; Hong and Kennett 2003 and others). The asymptotic theory of body-wave propagation in anisotropic media is also well developed (e.g., Crampin 1984; Thomsen 1986; Tsvankin 1997; Cerveny 2001; Chapman 2004).

The effect of initial stresses present in the medium is not considered in the above studies. Recently, Dey and Dutta (1998) have studied the problem of propagation and attenuation of seismic waves, taking the effect of initial stresses present in the medium into account. Biot incremental deformation theory has been used (Biot 1965) in their study. Selim and Ahmed (2006) have studied the velocities of propagation, damping, and attenuations of seismic body waves in compressible and dissipative medium under the effect of both initial and couple stresses.

Body-Wave Modeling

Seismological methods for determining Earth structure are often classified as being either active or passive in nature. Passive methods involve waiting for an earthquake to occur and provide the seismic source for recording. In contrast, controlled-source seismology refers to active methods where the experimenter provides the source by an explosion or a mechanical device such as a hammer, a weight that is dropped, or a vibrator. Active methods can, in turn, be divided into two basic classifications. The first is seismic reflection profiling, which is a clearly defined approach in which the goal is to produce an image of the subsurface in which structures can be seen directly, in the way that an X-ray image reveals features inside an object. Other active seismic methods infer seismic velocities and the presence of discontinuities in velocity and structure (such as faults) using a variety of approaches that analyze the arrival times and sometimes the shape of seismic waves traveling along different paths through the Earth. As a consequence of advances in seismic instrumentation and national programs increasing the number of instruments available, there have been many recent developments in these techniques that do not directly image the Earth. A convenient aspect of the theoretical basis for virtually all active-source techniques is that they are largely independent of scale. Thus, detailed studies to address environmental problems and regional studies to determine deep Earth structure employ the same basic techniques of analysis (Hancock and Skinner 2000). Recently, several efforts have been made to complete our knowledge of the structure of the

Earth's upper mantle by detailed observation of seismic body waves, especially by their amplitude–distance curves.

Definition

In the broadest sense, *borehole networks and arrays* are assemblies of *geophysical* instruments placed in the subsurface via boreholes. This article focuses on their seismological applications. While common usage often blurs the distinction between a *network* and an *array*, this article explicitly distinguishes between their operational theories and engineering practices, and in the case histories and examples provided. To strictly qualify as an *array*, the assembly of instruments must include matching or similar sensors located at different depths in one well or lateral separated in different wells. The combined natural-frequency responses and spacing of the sensors must also include a range over which they can be used to improve signal detection and analysis via time series processing. Outside of this range a *borehole* assembly acts as a *network* of independent detectors.

Introduction

The most common borehole geophysical instruments measure elastic and permanent displacements, electromagnetic fields, and fluid pressures. These sensors are used to variously record underground accelerations, velocities, tilts, tensor and volumetric strains, electrical conductivities, and pore pressures. While accelerometers, tiltmeters, and stainmeters are common borehole sensors, most borehole installations are currently done with seismometers.

The primary driver behind this application is the significant improvement in seismic signal quality with installation depth (e.g., Prevedel et al. 2015). Boreholes not only increase the distance of seismometers from near-surface environmental and cultural noise, they are also placed below the signal-trapping-and-attenuating properties of near-surface materials. As a result, borehole seismometers can dramatically improve the detection and location of natural and induced microearthquakes and enhance the quality of controlled-source data (e.g., Kwiatak et al. 2019). It has allowed the observation of phenomena such as fault zone guided waves (Ellsworth and Malin 2011). Recently, it has revealed the existence of resonances in fluid-filled fractures (Sicking and Malin 2019).

This entry describes some of the early developments in borehole seismology, its current instrumentation and installation methods, its noise-suppression and signal-detection advantages, and the differences between networks and arrays (e.g., Bohnhoff et al. 2018). It also presents representative examples and case histories that illustrate the key aspects of this method. The article concludes with a brief discussion of the new borehole fiber-optic sensor-cables method for borehole seismology. Such cables are showing promise in the measurement of seismic waves, rock strains, and subsurface temperatures and pore pressures (e.g., Lellouch et al. 2019). As their installation and analysis methods progress, it is likely that these types of sensors will become standard choices for borehole networks and arrays.

Early Developments

The general use of boreholes for making subsurface seismic measurements appears to have begun nearly 100 years ago. McCollum and LaRue (1931) report that “during the past year or more, use has been made of existent wildcat wells for the purpose of making a seismic exploration [of salt dome structures].” By the 1940s, use of a single borehole seismograph to profile the flanks of a salt dome was an established practice (Gardner 1949; Musgrave et al. 1960).

These developments parallel the first test of the borehole electric log by Conrad and Marcel Schlumberger in 1927 (Johnson 1962). The diversity of what became known as well logging tools grew rapidly, as did their use in make

point measurements of near-well rock properties and structures. The development of borehole seismic networks and arrays can be viewed as efforts to penetrate further into the rock mass for the same purposes. From this effort came the finding that placing seismometers even a few tens of meters underground significantly increased the quality of seismic data. These include increases in signal-to-noise ratios, recorded signal frequency bandwidths, and the detection and resolution of remote lateral velocity variations and structures.

Current Instrumentation and Installation

Examples of the type of seismic instruments used to achieve these advantages are shown in Fig. 1. In the case of traditional three-component, mass and spring sensors, these range from greater than ~ 10 – 12 Hz omni directional seismometers in fixed orthogonal mounts, to lower frequency ~ 1 – 10 Hz, gimble mounted, vertical and horizontal components. In both cases, the installed orientation of the components needs to be determined, either by special downhole tools or by calibrations shots or distant earthquakes. For a fixed depth installation, the latter two methods are most cost-effective.

In addition to the borehole sensors and their communication cables, a critical component of their deployment is the method used to couple them to the surrounding rock. This can be by cementing of the entire well, including instruments and cables. The disadvantage is that nothing is retrievable, and the well is permanently blocked. With this type of installation, the use of mechanically robust and electrically isolated sensors is essential: no active components requiring electrical power or corrodible materials, and triple barriers from sensor-compromising borehole fluids and gases.

For some applications an adequate degree of coupling can also be achieved by lowering the sensors on a heavy but flexible backbone – e.g., oil production tube – the spring action of which, when standing on the borehole bottom, pushes the sensors against the wall. This system is retrievable and works well for signals with accelerations significantly less than 1 g. Its disadvantage is the need for heavy surface equipment to handle the weight of the backbone plus sensors and cable. A more robust coupling alternative to a flexible backbone is the use of collapsible bladders or the equivalent of a firehose, the filing of which pushes the sensor against the borehole wall. Neither of these methods are suitable for moving the array along the well for profiling purposes.

For relocatable networks or arrays, passive coupling can be accomplished with bow-spring or magnetic clamps, the continuously coupled sensors pulled into the borehole by a heavy weight or mechanical tractor. The most sophisticated moveable couplers include electrically or hydraulically driven arms, the controlled forces of which guarantee the best connection to the borehole wall.

Noise-Suppression and Signal-Detection Advantages

Whether in the form of a borehole network or array, placing seismic receivers underground significantly improves the quality of seismic signals and the amount of information they contain about seismic events, velocities, and geological structures (Figs. 2 and 3).

Perhaps the most significant improvements are the increases in the signal-to-noise ratio and bandwidth of upward propagating seismic waves. As shown in Fig. 2a, several factors signal-to-noise improvement can be achieved by installing sensors just a few tens of meters of downhole. These improvements are most dramatic for signal frequencies above a few Hz, as these are most affected by attenuation and scattering near the earth's surface. Since these effects apply equally to downward propagating noises generated at the surface, their damping-out with depth adds to the improvement as well.

The combined effects on signal-to-noise and bandwidth can be seen in Fig. 2 by comparing the frequency-dependent improvements at depth with surface values: while it is not common to record 100 Hz seismic signals at ground levels, they are usually well recorded at a depth of 250–500 m.

These signal improvements have significant effects on the detection and location of small seismic events – both natural and fabricated. As shown in Fig. 2b, by lowering the sensors of an established seismic monitoring network tens to hundreds of meters below their current positions, the network's event-detection threshold can be lower by one to three magnitude units. Further improvements relate to more accurate determination of lateral velocity changes, observation of near-vertical structures, and the location of other subsurface sources – e.g., well drilling bits (Fig. 3).

Networks Versus Arrays

Data from multiple borehole sensors can be processed in two modes: as travel-time/ray path signals or as fully sampled waveforms. This distinction depends on the separation of the sensors, laterally or vertically, and the apparent wavelength of the signals to be processed. A simple rule that separates these two domains is given by Rayleigh's criterion – the rule of thumb being that sensors separated by less than a quarter of the apparent wavelength observed can be used in practical signal enhancement procedures. Otherwise the data must be handled as independent arrivals.

In the ray domain, borehole seismometer data have been used in two fashions: back-projecting rays to their sources based on P-wave polarization and S-P times and Kirchhoff migration studies of event amplitudes. In the waveform domain, signal-to-noise improvement have been accomplished

Borehole Seismic Networks and Arrays, Fig. 1 (a) An example of analog borehole seismographs for deployment in a hybrid, four-level vertical borehole array and seven-site lateral network configuration. These sensor arrays of 1, 2, and 15 Hz seismographs were deployed at 75 m spacing in each of the seven matching, 300 m deep, GONAF stations surrounding the eastern Marmara Sea (Prevedel et al. 2015; Bohnhoff et al. 2017.) While the seven stations are too far apart to be used as a lateral array for signal improvement methods such as beam forming, the arrays in each of the seven can be used to separate up-coming signals from down-going surface noise. These deployments can also be used to determine near-surface site effects as they impact earthquake locations (Raub et al. 2016). (b) An example of a multilevel Vertical Seismic Profiling array, with clamping arms extended. The

availability of electrical power for the clamps allows for the inclusion of digitizing and telemetry electronics in each of the 15 Hz-seismometer-based sounds. The spacing between levels can be adjusted from just a few meters to tens by changing the interconnects between levels. (c) An example of a marine hydrophone array – known as a streamer – rolled up on a reel. When deployed as a vertical array, the end of the streamer is anchored on the ocean floor and held vertical with a surface or near-surface buoy. (d) An example of a Fiber-Optic Distributed Acoustic Sensing (DAS) system. ((a) Modified from Prevedel et al. 2015; (b) courtesy of Section 4.2 ‘Geomechanics and Scientific Drilling’ at the GFZ German Geosciences Research Center, Potsdam, Germany; (c) https://commons.wikimedia.org/wiki/File:Streamer-detail_hg.jpg; (d) courtesy of J.-A. Chavarria, Horizon 2020)

Borehole Seismic Networks and Arrays, Fig. 2 (a) A typical range of signal-to-noise and bandwidth improvement for different frequency bands as a function of seismometer depth. This diagram, obtained from a variety of geological sites, shows the limited improvements resulting for burial of low frequency signals versus the significant one for high frequency ones. It also shows the increase in bandwidth versus depth. The width of the frequency band improvements is intended to cover the effects of different rock types and surface weathering and fracturing.

(b) Improvement in network detection and location capacity as a function of placing sensors below existing stations. The sequence of curved shapes is intended to show how elimination of near surface attenuation and noise by sensor burial lowers the network's threshold. In the example indicated on the right side of the diagram, a surface-based network that detects and locates ~M3 events at a given distance d can do the same for events one to two magnitude units lower by placing the networks sensors downhole modified from Bohnhoff et al. 2018

Borehole Seismic Networks and Arrays, Fig. 3 (Left) A schematic comparison between a surface array or network recording a subsurface seismic event (red dot) (upper left) and a borehole array or network (lower left). Blue triangles are sensors. The main advantages of the borehole installation are avoiding upward propagation through the attenuation and scattering of the near surface layers (e.g., Blakeslee and Malin 1990), attenuation and trapping of surface noise by these same layers, the appropriate geometry to record signals from vertical and subvertical structures,

and sensitivity to lateral velocity gradients. (Right) Improvements in event location at the SAFOD drill site: (1) are earthquake locations derived from (near) surface sensors (Zoback et al. 2011; E. Shalev, Personal Communication, 2003), (2) shows the refinement by the addition of the 32-level Pilot Hole vertical array (PHA, blue triangles) (Thurber et al. 2003), and then (3) by the subsequent installation of the Main Hole seismometer (MHS, large blue triangle). (Background color shows electrical resistivity structure modified from Unsworth et al. (1997).)

with various signal stacking and correlation procedures. It is important to note that in both domains it is essential that the orientation of the three component sensors be accurately known.

Even when processed as a network of sensors along a borehole versus as a signal-enhancement array, vertically separated seismometers have advantages such as identifying down-going surface noise from upcoming earthquake signals. For impulsive signals, this can be done by noting arrival orders. For long noise trains, it can be done by noting the lack of noise reaching the deepest sensors.

Illustrative Examples

Prime examples of borehole seismic networks made up of single-seismometer stations are government run local, national, and global monitoring systems. These include the high-resolution networks at Parkfield in California (Parkfield HRSN 2014) and Taipei in Taiwan (Huang et al. 2010). The most extensive national network is the constantly growing Japanese Hi-Net, with many hundreds of stations placed more than 100 m underground (Takahashi 1982; Hamada et al. 1985; Obara 2003). Global borehole network stations have served both research and international security needs. The borehole-based Seismic Research Observatory made

significant contributions to the study of the Earth's deep structure (<https://www.fdsn.org/networks/detail/SR/>). Many of the stations of the Global Seismic Network and Comprehensive Test Ban Treaty nuclear verification network are borehole-based (e.g., Bent 2013; <https://www.iris.edu/hq/programs/gsn>; Richards 2016; <https://www.ctbto.org/>).

In the ray domain, borehole seismometer strings like the one in the San Andreas Fault Observatory at Depth (SAFOD; Zoback et al. 2011) have been used in two forms: (1) back-projecting rays to their earthquake sources based on P-wave polarization and S-P times (Oye et al. 2004) and (2) Kirchhoff Migration studies of secondary arrivals originating from subvertical faults and other structures (Fig. 4a, b; Chavarria et al. 2003).

The ability of deep seismometer installations to accurately locate earthquake hypocenters is illustrated by the target event for the San Andreas Fault Observatory at Depth project (Fig. 3, right; Zoback et al. 2011; Thurber et al. 2004; Zhang et al. 2009; Unsworth et al. 1997). Initially, a large network of several dozen surface stations was used to establish a preliminary target event location using travel time tomography (Thurber et al. 2003). Shortly thereafter, arrival times from both earthquakes and explosions recorded on a 32-level string of borehole seismometers installed in the 2 km deep SAFOD Pilot Hole were added to the inversion (Thurber et al. 2004). The result was that the location of the target event moved some 700–800 m, mostly upwards, and less so to the

Borehole Seismic Networks and Arrays, Fig. 4 (a) The vertical component seismograms from the 32-level SAFOD 2 km deep Pilot Hole seismometer string. The signals are upcoming waves from an earthquake located on the San Andreas Fault. (b) A data set of both earthquakes and explosions were Kirchhoff migrated by Chavarria et al. (2003) to find potential reflection structures along the path of the SAFOD Main Hole. (c) Interferometric processing of SAFOD Main Hole Seismic

While Drilling data recorded on the Pilot Hole string to yield a clear reflection from fault structures within the San Andreas Fault Zone (Vasconcelos et al. 2008). The signals indicated by the red arrows are from structures inside the SAFZ system. As part of their analysis, Vasconcelos et al. (2008) also used Pilot Hole data to complete a wave field migrated image of the SAFZ structure. ((a and b) Modified from Chavarria et al. 2003; (c) modified from Vasconcelos et al. 2008)

southwest (Zoback et al. 2011; E. Shalev, Personal Communication, 2003). Afterwards, drilling of the SAFOD Main Hole (MH) was stopped short of this target to allow further location improvement by placing a seismometer at its bottom. The results were a further 200 m move mostly to the southwest.

An unexpected advance in fault zone velocity structure imaging at Parkfield came from borehole seismometer placed within tens of meters of the SAF (Ellsworth and Malin 2011; Malin: Fault Zone Guided Waves, this volume). These revealed head waves refracted along the faster side of the SAFZ (Ben-Zion and Malin 1991). In this same data set, there were clear, normally dispersed, fault zone guided waves (F_g). These fit Love-type trapped waves (F_L) propagating in a several km deep, ~100–120 m thick, low velocity channel (Li and Malin 2008). This picture was further refined by data from the SAFOD MH sensor, which contained Rayleigh-type trapped waves (F_R) and a new, leaky mode, fault guided wave F_ϕ . The latter phase fits partially trapped PSV waves travel in a several km deep, ~30 m wide fault core of very low P velocity.

A unique example of a local borehole-based network is the Geophysical Observatory on the North Anatolian Fault (GONAF) near Istanbul, Turkey (Bohnhoff et al. 2017). This seismic observatory is a hybrid network of borehole array stations, each station consisting of a four-level vertical array of seismometers spaced ~75 m apart, going up from ~300 m (Fig. 1a). The different levels has been used to follow up-coming and surface-reflected microearthquake signals for site effect studies (Raub et al. 2016) and to discriminate between down going surface noise and actual microearthquake signals (Malin et al. 2018). The former study uncovered a reversal in seismic velocities that grossly affected the motion of upcoming signals. In the latter, the noise suppression was used to lower the magnitude threshold by ~2–3 units, allowing detection of many microearthquakes preceding a 4.2 mainshock.

Some of the networks mentioned above can also be operated as arrays in a narrow range of signal frequencies, as in the case of surface wave analysis (Luo et al. 2008). However, lateral arrays and multilevel borehole sensor strings have been developed with the specific purpose of signal enhancement in mind (Fig. 1b). Early work in this type of Vertical Seismic Profiling in boreholes was begun in the 1950s by Y. I. Galperin (Galperin 1961; Galperin et al. 1986) and extensively expanded upon in the following decades (Balch and Lee 1984; Balch et al. 1986). The array aspects of lateral borehole networks have been extensively developed by the nuclear verification community (Richards 2016), primarily in the area of beam forming. These methods are now being adapted by energy industry seismic contractors (McClellan et al. 2018).

Full waveform signal-enhancement processing has also been applied to Seismic-While-Drilling data that was

collected with the Pilot Hole string during the drilling of the SAFOD MH. Using vibroseis-type deconvolution and seismic reflection signal processing methods, Coates et al. (2006) were able to obtain an image showing steeply dipping Tertiary Great Valley strata immediately south of the SAFOD site – an unexpected juxtaposition based on surface and area borehole geology. Because of their subvertical attitude and signal loss to near-surface attenuation and noise, this structure would have been difficult to image with standard surface reflection profiling. Further signal processing of the Seismic While Drilling data was done by Vasconcelos et al. (2008) (Fig. 4c). They used an interferometric approach to signal stacking to obtain an image of the internal structure within the fault zone.

In addition to downhole seismometers and accelerometers, multisensor hydrophone (streamer) arrays have been adapted for vertical deployments in boreholes on land and in the open ocean (Fig. 1c; Marzetta et al. 1988; Toksöz et al. 1992; Ikelle and Amundsen 2018). On land, early tests revealed that incoherent tube waves in long boreholes could completely cover secondary arrivals, initially limiting their usefulness. This problem was by and large solved by various signal processing and mechanical tube-wave-damping methods. Moreover, such arrays allowed detection of new seismic source processes related to migrating fluids and gases due to wellbore leakage (Bohnhoff and Zoback 2010; Bohnhoff et al. 2010; Martinez-Garzon et al. 2013). In the ocean, while near-bottom sensors are significantly quieter than near-surface ones, ocean currents can cause vertical arrays to tilt in various directions over minutes, hours, and days, making signal processing a challenge.

On land, the elimination of near-surface attenuation and suppression of surface noise has also allowed observation of what appear to be Krauklis wave resonances in subsurface fractures (Sicking and Vermilye 2019; Liang et al. 2017; Tary et al. 2014a, b). Figure 5a shows a spectrogram obtained by the stacking of frequency-time-amplitude data from a 12-level 2.5 km deep borehole seismometer string at a geothermal development site in Finland.

All these previous studies collected point-observation data using conventional borehole seismographic instruments: passive spring-and-mass and hydrophone sensors, force feedback, and similar nodal devises. Now on the near-horizon for broad application are borehole fiber-optic Distributed Acoustic Sensing (DAS) systems (Fig. 1d). A high-level account of this new technology was recently published by Lellouch et al. (2019). DAS systems have now effectively achieved continuous sampling of broadband seismic wavefields. Lellouch et al. (2019) have compared borehole DAS observations of earthquake and explosion data from multichannel VSP instruments at the SAFOD site. Their analysis included travel time picking, slant stack beam forming, and interferometry. Due to its redundancy, it was

Borehole Seismic Networks and Arrays, Fig. 5 (a) Spectrogram of resonances from major subsurface fractures recorded by a 12-level borehole seismometer string during hydraulic stimulation of a geothermal well in Finland. The string was placed between 1970 and 2420 m below ground and ~3600 m above the stimulation zone. While the resonance could be seen on individual-level spectrograms, the current plot is the stack of spectrograms from 11 levels. Based on the work of Tary et al. (2014a, b) and Liang et al. (2017), and correlations with stimulation pumping and induced earthquakes, Sicking and Malin (2019) have interpreted these signals as coming from interfering

Krauklis wave on major subsurface fractures (Figure courtesy of P. E. Malin 2019). (b) Broadband Fiber-Optic DAS recordings of M1.33 and M2.4 earthquakes on the San Andreas Fault at Parkfield. These data were collected with a DAS cable along the first 800 m of the SAFOD Main Hole. The data have been bandpass filtered between 0 and 120 Hz. Compared to the point observation data in Fig. 4a, b, these data meet the 1/4 wavelength criterion for high-frequency signal enhancement. The result is a nearly continuous wavefield image that provides a much richer look at the velocity structure surrounding the drill site and SAF. (Figure from Lellouch et al. 2019)

possible to detect both S-waves and clear P-S reflections in the DAS data (Fig. 5b). In addition to the technical description of DAS operation, their paper includes important velocity and structural results from SAFOD.

Conclusions

Progressing from a single spring-mass seismometer in shallow water well to continuous Fiber-Optical DAS cables over the past 100 years, borehole seismic networks and arrays have opened up a previously unobtainable view of the earth's interior. It facilitates the detection and monitoring of deep and remote, and otherwise inaccessible, seismic events and tectonic processes. This includes the signals of very small earthquakes, very large explosions, and, now, evidently, resonances in fractures stimulated by hydraulic pumping. Used to image geological resources, tectonic structures and potentially hazardous faults, borehole seismology allows for less

intrusive remote exploration of the crust and refinement of seismic hazards and risks.

With further technological and methodological improvements, downhole seismic networks and arrays may become the norm of high-quality seismic observations. This evolution is currently taking place with the advent of Fiber-Optic DAS systems. Combined with lowered costs in drilling and the needs for a more fundamental understanding of the earth and its resources and hazards, borehole seismic networks and arrays are likely to be the next step in the history of seismology.

Characteristic Earthquakes and Seismic Gaps

David D. Jackson and Yan Y. Kagan
Department of Earth and Space Sciences, University of
California Los Angeles, Los Angeles, CA, USA

Definition

Fault slip	Relative motion, either steady or sudden as in earthquakes, between rock units on either side of a fault.
Rupture	Sudden fault slip in an earthquake.
Elastic rebound	Sudden release, as by an earthquake, of slowly accumulated strain energy.
Segment	A section of a fault or plate interface bounded by features thought to serve as strong barriers to earthquake rupture. Features postulated to form such barriers include changes in fault orientation or in rock type across parts of the fault, and intersections with other faults.
Characteristic earthquake	An earthquake rupturing an entire fault segment. Alternately, one of a sequence of earthquakes rupturing the same area of fault.
Recurrence interval	The time between characteristic earthquakes on a given segment or fault area. <i>Quasiperiodic</i> Occurring at approximately equal recurrence intervals.
Seismic cycle	A sequence of events on a segment starting with a large earthquake, followed by aftershocks, then by steady stress accumulation, and culminating with another large earthquake. The term “cycle” is sometimes but not always meant to imply quasiperiodic recurrence.

Seismic gap A segment for which the time since the previous characteristic earthquake approaches or exceeds the average recurrence interval.

Introduction

The seismic gap hypothesis holds that most long-term geologic slip on faults or plate boundaries is accomplished by characteristic earthquakes on segments. Such quakes are presumed to reduce the stress substantially, necessitating a substantial recurrence time for elastic stress to recover before the next characteristic earthquake. The dates and rupture extent of past earthquakes may be determined by modern seismic networks; by historic reports of faulting, damage, or strong shaking; or by paleoseismic investigation of trenches across faults. The average recurrence time may be determined either from a sequence of dates of past characteristic earthquakes, or by the time required for steady slip on a fault to accumulate the slip experienced in a characteristic earthquake (Working Group on California Earthquake Probabilities 1988, 1990).

History

Well before plate tectonics became accepted in the 1960s, Gilbert (1884) argued that large earthquakes should be separated by substantial time intervals. Reid (1910, 1911) proposed that faults slowly accumulate energy later released suddenly by earthquakes (“elastic rebound”), and that the time to a future earthquake could be estimated by surveying the strain released by a previous one. Fedotov (1965) noticed that most of the Kamchataka–Kurile trench in the northwest Pacific had been ruptured by earthquakes in the early twentieth century, with the exception of one zone southeast of Hokkaido. He concluded that a future earthquake was likely in that area, a forecast realized in 1973 when the Nemuro-oki earthquake struck with magnitude about 7.5 (Kasahara 1981, 182).

Plate tectonics now provides a compelling, steady source of the strain energy driving elastic rebound, and that fact led many to conclude that occurrence of large earthquakes must be separated by enough time to allow recharge. Scholz (1990, 260) remarked that “A tenet of plate tectonics is that the rates of plate motion must be steady over geologic time periods and must be continuous along plate boundaries. If it is assumed further that a significant portion of this motion must be released seismically, then it follows that segments of plate boundaries that have not ruptured for the longest time are those most likely to rupture in the near future. These places are called seismic gaps.” The seismic gap hypothesis was celebrated when Nishenko (1989) published a list of 13 earthquakes that fit, at least approximately, the descriptions of previously expected earthquakes.

The seismic gap model has been applied to long-term forecasting of earthquakes in many regions (Sykes 1971; Kelleher 1972; Kelleher et al. 1973; McCann et al. 1979; Working Group on California Earthquake Probabilities 1988; Nishenko 1991). The model and its definition have evolved along with the quality and quantity of data that go into it. Fedotov (1965) defined the Nemuro-oki gap as the last remaining unbroken segment. McCann et al. (1979) used elapsed time and a color code to label segments around the Pacific Rim: more than 100 years had elapsed in red gaps, between 30 and 100 years in orange gaps, and less than 30 years in apparently safe green zones. In the most comprehensive forecast ever using the seismic gap model, Nishenko (1991) actually made testable probabilistic forecasts for about 125 plate boundary segments around the Pacific Rim. In that study he estimated the mean recurrence time and the elapsed time for each segment, and assumed that their ratio obeys a log-normal probability density function. With that information, he calculated the probability that each zone would be ruptured by a characteristic earthquake whose magnitude he also listed for each zone within 5-, 10-, and 30-year periods. A very similar model was used by the Working Group on California Earthquake Probabilities (1988) in its official earthquake probability estimates.

Assumptions

All the applications mentioned above share several important assumptions. First, their authors assume that faults and plate boundaries are segmented and that rupture does not cross segment boundaries. Second, they assume that each characteristic earthquake ruptures to both ends of its segment, reducing the stress to a uniform base level and beginning the process of stress recharge. Third, they assume that the time to the next characteristic earthquake depends almost entirely on the time of the previous one: not on other

earthquakes, nonelastic stress redistribution, or other causes. To make useful forecasts, scientists must obviously be able to distinguish characteristic earthquakes from all others in order to know the elapsed time since the last one.

Small Characteristic Earthquakes

Recent studies in California (e.g., Nadeau and McEvilly 1999), Japan (e.g., Igarashi et al. 2003; Okada et al. 2003), and elsewhere have identified sequences of small earthquakes fitting the alternative definition of “characteristic earthquake” above. In each sequence, the events are approximately the same size, and rupture approximately the same fault area. They recur at nearly equal time intervals or in some cases variable intervals consistent with variations in their size or in fault slip rate. In most cases, the slipped areas appear to be surrounded by areas where displacement occurs by steady slip rather than earthquakes. Because of that special circumstance, these small repeating earthquakes are not relevant to the discussion of seismic gaps.

Modified Seismic Gap Hypothesis

As time, earthquake experience, and theoretical sophistication have accumulated, earth scientists have modified the seismic gap theory to rely less on the assumptions above. The Working Group on California Earthquake Probabilities (1990) allowed adjustments to account for stresses from earthquakes not on the relevant segment. The 1992 Landers, California earthquake (magnitude about 7) presented a particularly important observation. In that event, rupture jumped segment boundaries and even faults, making use of up to five faults mapped as separate before 1992. In a seismic hazard model produced by the Southern California Earthquake Center (Working Group on California Earthquake Probabilities 1995), the seismic gap model was modified to allow rupture to jump segment boundaries with a modest probability. Later uses of the seismic gap model in California for official hazard estimates employ increasingly complex assumptions, especially about conditions under which rupture is likely to involve more than one segment (Working Group on California Earthquake Probability 2002, 2008).

The more complex versions of the model raise interesting questions. What truly constitutes a segment? How effective are weak barriers in stopping rupture, and what controls their strength? Are the boundaries fixed in space, or can they move as stress conditions change? When rupture crosses a boundary, does it consistently continue to the next? If not, does it reset the stress and the clock on the partially ruptured segment? Do the elapsed times on adjacent segments control the

probability that rupture will jump the barrier between them? If so, which segment is most important? Modelers must answer these questions, implicitly or explicitly, to forecast using the modified gap models. So far, there is no clear consensus on the answers.

Challenges to the Seismic Gap Model

Despite some reported successes, the seismic gap hypothesis has often been questioned. Critics point to the difficulty of verifying the rather strong assumptions behind the hypothesis, and to its limited success in forecasting earthquakes.

The basic assumption that faults and plate boundaries are segmented has provoked significant debate. Even the few apparent successes (e.g., Loma Prieta, CA, 1989; Parkfield, CA 2004; Chile, 2010), are equivocal at best. The rupture of the Loma Prieta earthquake was about the length of the nearest segment mapped by the Working Group on California Earthquake Probabilities (1988), but it shifted south and spilled over the southern segment boundary. Moreover, the event occurred near, but not actually on the San Andreas Fault for which the segment was defined. Before 2004, the Parkfield segment was defined in several different ways, so its location at Parkfield does not confirm the segmentation hypothesis (Jackson and Kagan 2006). The 2010 Chile earthquake went well beyond the segment boundaries specified by Nishenko (1991). In addition, several events have clearly violated pre-assigned boundaries. The 1992 Landers quake was mentioned above, and the great Sumatra tsunami earthquake of 2004 breached several boundaries along its 1300-km rupture zone (Nalbant et al. 2005).

The assumption that earthquakes rupture to both ends of segment boundaries also lacks verification. A basic problem is that the locations of segment boundaries are usually estimated inaccurately from the extent of past earthquake ruptures. For earthquakes identified by paleoseismic investigations, rupture can generally be pinpointed at only a few widely spaced locations. For historical earthquakes, rupture extent is typically estimated with great uncertainty from the extent of damage or reported shaking. Even for modern instrumentally recorded earthquakes, the extent of the after-shock zone or fault scarp may not accurately represent the rupture at depth where the elastic rebound occurs. In many cases, the extent of rupture for older earthquakes is assumed to be similar to that of the most recent event, a clear case of circular reasoning.

The connection between plate tectonics and earthquake recurrence referred to in the words of Scholz above depends on the assumption that characteristic earthquakes release most of the slowly accumulated fault slip. However, that assumption fails in many examples. For instance, the cumulative slip of the

Parkfield, CA earthquakes since 1857, often regarded as an archetypal characteristic sequence, accounts for only a small fraction of expected slip at the long-term geological rate (Jackson and Kagan 2006). In such cases, the alternative definition of characteristic earthquakes listed above, and the times of past events, may provide valuable information on the causes of some earthquakes but the direct link to plate tectonics is lost.

Proponents of the seismic gap theory cite many examples in which identified gaps have been filled by earthquakes. The positive examples are appealing but insufficient for two reasons. First, the definitions of gaps and forecasted earthquakes were quite general, making the target easier to hit at random. Second, they included only successes; a fair evaluation needs to consider failures as well.

Kagan and Jackson (1991, 1995), and Rong et al. (2003) applied statistical tests to the seismic gap theory as articulated by McCann et al. (1979) and Nishenko (1991). Earthquakes were actually more frequent in McCann's green zones than in the red ones, opposite to what the gap theory assumes. The 1991 gap model implied far more earthquakes, in different places, than actually occurred. Kagan and Jackson (1995) and Rong et al. (2003) also tested a simple alternative to the gap model, assuming that earthquakes occur randomly in time and near past earthquakes. The alternative model fits the total number and the locations of future earthquakes much better than the 1991 gap model.

These statistical tests necessarily applied to the earlier versions of the gap hypothesis, in which segments were assumed to be independent of one another. Since then, more complex versions of the model have been applied. Most of these applications involve one or a few purported gaps with estimated recurrence times of decades or centuries. Published models generally do not provide probabilities for multi-segment ruptures, and they cannot be effectively evaluated until several seismic cycles have elapsed. To be rigorously testable, such a model must forecast a few tens of well-defined earthquakes. Unfortunately, no systematic, well-specified version of the more complex seismic gap model has been applied broadly enough to be tested.

Conclusions

The intuitively appealing seismic gap model encompasses the virtually unassailable principle that earthquakes release strain energy accumulated over a long time. Although many large events have occurred in previously identified gaps, the same is true of locations outside them. Simple versions of the gap theory, in which characteristic earthquakes occur on independent segments, are no longer tenable. Modified versions of the gap theory have not yet been formulated in a rigorously testable way.

Continental Crustal Structure

Rolf Meissner (Deceased) and Hartmut Kern
Kiel, Germany

Definition

Seismic reflection and refraction profiling supplying velocity-depth functions and relations to petrology is the key to probe the continental crust.

Introduction

In the last 20 years, much progress has been made in the development of geophysical techniques that increased our knowledge about the variability of crustal structure substantially (see ► [“Deep Seismic Reflection and Refraction Profiling”](#)). A big misunderstanding, still often presented today, is the use of the phrase “the” crust. This is a marked oversimplification. Continental crust has been found to be extremely different (Christensen and Mooney 1995; Mooney 2015; Rudnick and Gao 2014; Hacker et al. 2015). There are at least three main types to be distinguished (see ► [“Lithosphere, Continental”](#)).

1. Thick, old cratons, shields, and platforms
2. Orogens, often related to continental subduction
3. Extensional areas, including shelves and rifts

Thick Precambrian cratons, disrupted by early plate tectonics, are presently found in all continents; they contribute more than 70% to the continental lithosphere. They are characterized by a thick crust (45–50 km) with high velocities (>7.2 km/s) in the lower part. The two other crustal types were generated by modern plate tectonics: the *orogens* by convergence and plate collisions, most of them showing deep crustal roots, and the *extensional areas* by divergence and wrench tectonics, often accompanied by thermal and magmatic processes. They generally show a shallow crustal thickness without a high-velocity lower crust. Special forms are rifts, basins, and igneous provinces.

Type sections of the three main crustal structures are presented in Fig. 1.

In general, the continental crust has lower seismic velocities and consists of lighter material than the underlying mantle; V_p is smaller than 7.8 km/s, V_s smaller than 4.3 km/s, and ρ below 3.1 g/cm^3 . Crustal thickness is between 20 km (shelves) and more than 70 km (some orogens) (Mooney et al. 2005). Mohorovičić was the first to determine the base of the crust, today called the “Moho” for short. It is observed worldwide and is clearly recognized by seismic methods. It is worthy to note that the position of the seismic Moho is not always identical with the petrological Moho (defined as the boundary between non-peridotitic crustal rocks and olivine-dominated rocks). In case that mafic rocks are transformed into eclogites at the base of orogenically thickened crust, P-wave velocities of eclogites largely overlap with those of peridotites so that seismic field studies may not detect eclogites as crustal rocks (e.g., Mengel and Kern 1992; O’Reilly and Griffin 2013). An intracrustal boundary – the “Conrad” – seems to separate upper sialic from more mafic lower crust in some areas. Transport of crustal material into the mantle and delamination of the lithosphere and the lowermost part of a thickened crust may give rise to a reduction of crustal thicknesses.

Continental Crustal Structure, Fig. 1 Type sections of the three main crustal structures (a–c) and ranges of P-wave velocities in the upper, middle, and lower crust. Numbers are velocities in km/s

Methods

Reliable studies of the continental crust were started in the last 40 years by seismic methods, applying first refraction studies with man-made explosions and lines of simple geophones. Wide-angle reflection seismics followed, and steep-angle reflection seismics became more and more important (see ► “[Deep Seismic Reflection and Refraction Profiling](#)”). In the last 30 years, digital technology, computer programs for ray tracing and tomography, and large, national, and international research programs with an increased number of recording devices and energy sources were initiated. Large, national reflection programs, often with a substantial support by the industry or large funding agencies, were developed in nearly all industrialized countries, spearheaded by COCORP in the USA. Both methods – refraction-wide-angle and steep-angle reflection – complement each other, the former supplying velocity-depth functions and relations to petrology and the latter providing reflectivity images of the subsurface that reveal past tectonic processes. Both methods form the backbone of crustal interpretation. They confirmed identical Mohos, either by a jump of velocities or by termination of (crustal) reflectivity because the mantle is less reflective (Meissner and Brown 1991). Vibroseis and dynamite shooting are used for reflection programs, the latter one generally providing a higher energy output, which is sometimes used for piggy-back wide-angle work. In the last 20 years, a relatively cheap seismological method, the “receiver function method” (see ► “[Seismic, Receiver Function Technique](#)”), supported interpretation of seismic data, making use of global seismicity and a wave change at seismic boundaries. This “receiver function method” is based on seismic phase conversions of teleseismic waves at the Moho and at boundaries in the crust and mantle.

Non-seismic geophysical techniques are complementary to seismic methods: gravity, for instance, for investigating isostatic problems or selecting between competing seismic interpretations or – together with magnetics – looking for inhomogeneities or controlling structure. Electromagnetic and magnetotelluric methods help to find and to interpret conductivity anomalies. Measurements of heat flow help to observe heat sources and decipher the thermal or magmatic history of a specific area. Depending on the heat flow, temperature-depth functions and viscosities that control rheology can be estimated. The brittle upper crust extends to a depth of 12–20 km and is a zone where generally earthquakes occur. It is separated from the more ductile, aseismic part of the middle and lower crust (some exceptions). Various experimental studies of creep, stress, and strength support seismic interpretation.

Cratons

Cratons are relatively stable Precambrian continental units with a rather deep lithosphere (Fig. 1a). They are called

shields when a sediment cover is lacking and platforms when covered by sediments. Today, cratons are found in all continents, possibly created from a few early supercontinents that were later disrupted by plate tectonics. No consensus exists about the number of cratons. They comprise up to ten in Africa and even more in North America. The latter were finally combined into the big “North American Craton” forming the whole interior of North America (without its margins in the west and east). Even “stable” cratons are influenced by Proterozoic and Phanerozoic processes like rifts or plumes. In North America there is a 2500-km-long Proterozoic midcontinental rift with a thick cover of sediments and volcanic intrusions and a reduced crustal thickness. There are also Paleozoic rifts in the southern part of the East European Craton, and there is an unusual 60-km-thick crust in the cold Baltic Shield, well within the eclogite stability field in the lowermost part. However, high velocities (> 7.8 km/s) corresponding to eclogitic rocks are not observed in the lowermost crust of the Baltic Shield (Korja et al. 2009).

The crystalline crust of cratons is similar worldwide. Cratons are characterized by low heat flow values. Their thickness is in the range 35–55 km with a “classical” three-velocity structure (Pawlenkova 1996), as shown by “deep seismic sounding” (wide-angle plus refraction studies). In general, cratons have an upper crust with V_p around 6 km/s, a middle crust around 6.5 km/s, and a roughly 10-km-thick lower crust with velocities around 7.0–7.2 km/s, sometimes 6.7–7.5 km/s (Fig. 1a). A typical example is the EUROBRIDGE profile (Guterch et al. 1997) crossing the crust of the East European platform (Fig. 2).

Reflection seismic experiments generally show no special enhancement of reflectivity in the (mafic) lower crust, as shown by the large transects of LITHOPROBE in Canada,

by the COCORP data in the USA, or by the BABEL surveys in the northern Baltic Sea (some exceptions).

Orogens

Collisions of plates or terranes create orogens by compressing material upward (mountain ranges) and downward (roots), and dynamic processes initiate oceanic or continental subduction. While the elevation of an orogen apparently depends on the time and speed of the colliding plates (e.g., Himalaya, Tibet), processes of crust/mantle interaction are quite complex. Magmatic processes are found behind subducting plates in many orogens (Alps, Sierra Nevada, Andes). In continental collision zones, rock types of the lower crust resemble those of the neighboring plates, guided into the orogens. There are high-velocity (cratonic) crustal rocks with a mafic lower crust in the Uralides (from the East European platform) and sialic, extensional crusts with a reflecting lower crust in the Alps (mostly from the Variscides). Continental subduction often follows oceanic subduction. Remnants of these processes may be reflected by the crustal “roots” (see ► “[Seismic, Reflectivity Method](#)”). Figure 3 shows simplified cross sections through the Alps and Pyrenees. Orogens are more or less isostatically compensated, and its Bouguer anomaly is strongly negative (Ebbing 2004).

Extensional Areas

Extensional processes cover many dimensions: from rifts, basins, (the basin and range of North America), and continental shelves up to large Phanerozoic areas like

Continental Crustal Structure, Fig. 2 Typical cratonic crust from the East European platform (after Guterch et al. 1997)

Continental Crustal Structure, Fig. 3 Typical sections of orogenic crust (Alps and Pyrenees)

Europe and west of the Teisseyre-Tornquist line (see ► [“Trans-European Suture Zone”](#)). This large extensional area was created in post-Avalonian and post-Variscan time at the end of the Paleozoic. A surprisingly uniform crust has been formed, showing three prominent differences compared to the cratons: their thickness is only 30 km (Fig. 1c), their velocities are lower than 6.8 km/s, and in many places, they show prominent reflectivity (lamellae) in the lower crust.

Apparently, all three characteristic crustal patterns are genetically interrelated. While a former lower crust (in the basin and range province and in the Variscides) got lost in the previous orogeny (by delamination or subduction),

subsequent moderate, but widespread, extension dominated. Mafic-ultramafic dykes intruded into the lower crust and formed sill-like intrusions, giving rise to high impedance contrasts after cooling. Importantly, sills are mostly rather thin and do not generally increase the lower-crustal overall (sialic) seismic velocities. Figure 4 gives an example of strong lower crust reflectivity and low average velocities.

In contrast, the formation of rifts and basins is a result of local (extensional) stress and/or strong local heat anomalies. As a consequence, large volumes of mantle-derived basaltic magmas intrude into the crust and after cooling the mafic rocks (gabbros or metamorphic equivalents) cause the

Continental Crustal Structure,
Fig. 4 Multiple reflections
 (laminations) in the Moldanubian
 lower crust along the DEKORP II
 line, along with ranges of V_p
 velocities at different depths

observed high velocities at the base of most rifts and basins. Examples are the Oslo Graben, the Danish Basin and other adjacent rifts and basins north of the Variscan front, the great East African Rift, the Donetz Basin, and the midcontinental North American rift. In general, the massive intrusions created a transparent lower crust, but some basins with high lower crust velocities (above 7.2 km/s) show some thin lamellae (apparently ultramafic) on top of the Moho. Also in some areas of continental/ocean transition, high-velocity lamellae are observed in the lower crust (Roberts et al. 2009).

In general, lower crustal reflectivity seems to depend on the volume and thickness of the mafic intrusions compared to the host rock. Whereas sill-like intrusions are suggested to generate the observed lower crustal reflectivity, massive intrusions in the lower crust reduce reflectivity and enhance the average velocities to values of 6.8–7.2 km/s. The volcanic Messum ring complex in Namibia shows no lamellae in the high-velocity interior but a good reflectivity in the surrounding (Bauer et al. 2003). In contrast, the Viking Graben in the North Sea shows lower crust reflectivity and no reflection around it (McBride et al. 2004).

Most continental shelves show extension and a stretched continental crust with a thickness of only 20–30 km, often containing aborted rifts (Korja et al. 2009). Reflectivity in the lower crust is found in the West Atlantic margin (Faroe or Hatton) and along the Greenland coast. Often, seaward dipping reflections, caused by intrusive and extrusive magmatism, mark the onset of oceanic crust with high velocities. BIRPS WAM – profile from the British Isles toward the

Atlantic Ocean – shows a preferred lower crust reflectivity below the (continental) Mesozoic basins, while the oceanic crust is free from reflections.

Constraints on Crustal Petrology

The measured seismic velocity structures are very helpful in providing a rough characterization of the Earth's crust in different tectonic environments, but they are nonunique so that inferences about composition cannot be drawn from wave velocities (at least P-wave velocities). The seismic properties at depth are determined by a number of lithologic and physical factors that control the in situ rock properties in a very complex manner. Velocities are controlled by the intrinsic properties of the rocks (mineralogical composition, chemical composition, metamorphic grade, crystallographic preferred orientation of constituent minerals, etc.) and by the physical environment of the crust (temperature, pressure, porosity, fluid content, etc.) (see ► “Seismic Properties of Rocks”).

Direct information about the composition and structure of the deep crust can be obtained either from crustal terrains exposed at the surface (e.g., Fountain and Salisbury 1981; Kern and Schenk 1988) or from xenoliths brought to the surface by magmas (Downes et al. 1990). Deeply eroded Precambrian terrains (e.g., Sri Lanka) and upthrust tectonic slices in orogenic belts (e.g., Ivrea Zone, N. Italy; Serre Mountains, S. Calabria; Kapuskasing Zone, Canada)

provide perhaps the best geologic guides to structural style and composition at depth. Such rocks are important in providing direct data although they contain a mixed message as they are no longer the in situ deep crust.

A unique ability to correlate the seismic data with the structure and composition of the in situ deep crust can be provided by coupling experimentally determined or calculated P- and S-wave velocities for relevant crustal rocks collected from surface outcrops or from xenoliths, simulating in situ conditions: (1) by laboratory seismic measurements at actual PT conditions (e.g., Christensen and Wepfer 1989; Kern et al. 1999; Ji et al. 2015) and (2) by calculations from modal analyses and elastic properties of the rock-forming minerals and their pressure and temperature derivatives (e.g., Jackson et al. 1990; Barruol and Kern 1996; Almquist and Mainprice 2017).

High P-wave velocities (>6.9 km/s) generally defining the lowermost crust (below about 20–25 km depth) are typical for metamorphic rocks in the granulite facies. These are mafic granulites, mafic amphibolite facies rocks, anorthosites, and high-grade metapelites.

Intermediate P-wave velocities (6.5–6.9 km/s) represent the upper-lower to mid-crust and are characteristic for intermediate granulites and metapelites.

Low P-wave velocities (6.2–6.5 km/s) occurring at mid-crustal levels in Paleozoic and more recent fold belts and in the uppermost crust in shields and platforms are likely to be composed of felsic rocks in the amphibolite and granulite facies. It should be noted, however, that not all felsic (granitic) upper crustal rocks are intermediate- to high-metamorphic grade. The Superior Province (Canada) is an example of low metamorphic shield rocks.

Mineralogically, feldspar (K-feldspar, plagioclase) is the most abundant mineral, followed by quartz and hydrous minerals (such as mica and amphiboles).

The bulk chemical composition of the upper crust is felsic, and the middle crust is intermediate in composition. The average composition of the lower crust is in general mafic in cratons, but it tends to be intermediate or even felsic in some regions. The continental crust as the whole (average of all crustal types) is suggested to be intermediate in average bulk composition (Rudnick and Fountain 1995; Mooney 2015).

Importantly, most of the rocks constituting the Earth's crust exhibit marked anisotropy of elastic properties (e.g., Kern et al. 2001; Ji et al. 2002; Almquist and Mainprice 2017). Typical values of intrinsic P-wave anisotropy (quartz-mica-schists, felsic gneisses, granulite-facies metapelites, amphibolites) range from 5.4% to 10.7%. Anisotropy may be caused by crystallographic (CPO) and morphological (or shape) preferred orientation (SPO), by oriented microcracks or by thin layers of otherwise isotropic materials with different properties (see ► “Magnetic Anisotropy”).

Whereas oriented cracks may contribute a large fraction of observed seismic anisotropy in the uppermost crust (Crampin 1987; Crampin and Gao 2018), CPO- and SPO-related seismic anisotropy is a major contribution in ductily deformed and foliated crustal structures (shear zones, gneiss sections) of the deeper crust. It is mainly due to the alignment of mica and hornblende minerals and their strong single crystal anisotropies (Barruol and Kern 1996; Meissner and Kern 2008). In addition to mineral and chemical composition and rock fabric, pore fluids may have an important bearing on in situ seismic properties. Saturation of pore space ($P_{pore} \approx 0$) increases V_p , whereas V_s remains unaffected (Nur and Simmons 1969). In case of pore pressure approaching lithostatic pressure ($P_{pore} \approx P_{lith}$), microcracks and grain boundaries are more or less kept open. As a consequence, both P- and S-wave velocities are smaller than in dry rocks, due to a reduction of the effective pressure ($P_{eff} = P_{lith} - n \times P_{pore}$; $n \approx 1$). Importantly, V_p anisotropy is significantly higher in dry rocks than in water-saturated rocks at atmospheric pressure conditions (Popp and Kern 1994). As pressure is increased, differences progressively decrease. The corresponding S-wave velocities and S-wave splitting data are only weakly affected by intergranular fluids.

Seismic anisotropy is becoming increasingly important also in understanding the evolution of the Earth's crust (and upper mantle). Since the measured seismic anisotropy has a structural (macro- and/or micro-) origin, seismic azimuthal anisotropy manifested by shear wave splitting, in particular, can provide important geophysical evidence of deformation because the orientation and magnitude of anisotropy are, in general, strongly related to the internal strain-induced rock fabric. Although variations of lithology are suggested to be most important for the generation of seismic reflections in the lower crust (laminated lower crust) (e.g., Meissner et al. 2006), seismic reflectivity (Warner 1960) may be enhanced by the fabric-related anisotropy of ductily deformed structures (Kern and Wenk 1990; Vasin et al. 2017). It should be noted, however, that in crustal rocks, the variability due to variation in composition is generally higher than the variation caused by velocity anisotropy (except for schists). The reverse is true in the olivine-rich upper mantle rocks. This probably implies that on a regional scale, fabric-related anisotropy is more important in the oceanic and continental upper mantle than in the continental crust.

Summary

Seismic refraction and reflection surveys have revealed three main types of continental crust: (1) the thick old cratons, constituting large parts of all continents; (2) the orogens, generated by plate collisions; and (3) the extensional areas with a relatively thin crust, exhibiting ample reflectivity

(lamellae) in the lower part. Crustal thickness is between 20 km (shelves) and more than 70 km (some orogens). The Mohorovičić discontinuity (Moho), defined by a jump in velocity and density, separates the lowermost crust from the upper mantle. High P-wave velocities (>6.9 km/s) are typical for the lowermost crust of platforms and orogens; they stand for high-grade mafic rocks in the granulite facies. In the thin lower crust of extensional areas, high-velocity mafic rocks are almost lacking. The upper-lower to mid-crust is characterized by intermediate P-wave velocities (6.5–6.9 km/s) and is likely to be composed of intermediate granulites and metapelites. Low P-wave velocities (6.2–6.5 km/s) of mid-crustal levels in Paleozoic and more recent fold belts as well as in the uppermost crust in shields and platform point to felsic rocks in the amphibolite and granulite facies. Seismic anisotropy is an important property of most rocks constituting the Earth's crust. It is basically caused by crystallographic and morphological (or shape) preferred orientation, by oriented microcracks, or by thin layers of otherwise isotropic material with different properties.

Continental Drift

Alan G. Smith
(Deceased)

Definition

Continental drift The name given to the relative movement between continents.

Introduction

Apparently, continental drift was first postulated by Abraham Ortelius, who made one of the first atlases, in the third edition of his *Thesaurus Geographicus* (Ortelius 1596) to account for the similarity between the coastlines of western Africa, western Europe, and the eastern Americas. During the next three

centuries or so, several other thinkers used this morphological similarity to come to the same conclusion.

Alfred Wegener

Although Ortelius speculated that earthquakes and floods had torn the continents apart, Alfred Wegener, an Austrian meteorologist, was the first to systematically gather the geological evidence for continental drift in his synthesis (Wegener 1929a), also translated into English (Wegener 1929b), parts of which had been published as early as 1912 (Wegener 1912).

Wegener was puzzled in particular by the present-day distribution of former ice-age deposits, or tillites, of Permo-Carboniferous age, now known to be about 300 million years old that are found today in South America, Africa, Antarctica, India, and Australia. Wegener's meteorological background led him to assume that the present-day climatic zones, with cold polar regions and a hot tropical belt, was a fundamental property of the Earth's atmosphere that had been established before these glacial deposits had formed and had persisted to the present-day. He realized that if all the southern continents had been joined together to form a supercontinent lying near the south geographic pole, then the *present-day* distribution of all the Permo-Carboniferous tillites would have a logical explanation. This supercontinent is known as Gondwana. But Wegener went further and postulated that the northern continents had also been joined to form a northern supercontinent known as Laurasia, which, with Gondwana, formed a huge continental area incorporating all the major continents, known as Pangea.

Wegener's solution to the tillite distribution had a compelling elegance about it, partly because it also placed the Carboniferous forests of Europe and North America, (whose compressed remains gave the name to the Carboniferous period) in what would have been the tropical region of that time. However, elegance is not a scientific proof, and Wegener's ideas were rejected by most geophysicists and many geologists, principally because there were no physical measurements that demonstrated drift and there was also no known *physical* mechanism that could move continents independently of one another (e.g., Jeffreys 1929).

Wegener (1929a) made the reassembly by positioning the continents at where he presumed the edges of the continents lay, that is, somewhat beyond the present-day coastlines, but his maps were rather schematic. A more convincing Gondwana map, supported by much geological evidence, was made by Du Toit (1937), but the best precomputer map showing the excellence of the fit between the continental edges of South America and Africa was made by Carey (1958). Jeffreys (1964) denied that there was a fit, and it was his denial that in part led Bullard and others to examine how well the continental edges fitted

together (Bullard et al. 1965; Everett and Smith 2008). These ideas were supported by the changes in the Earth's magnetic field preserved in rocks (see ► [“Paleomagnetism, Principles”](#)) determined by workers such as Irving (1964), but the results were *not fully accepted by the geoscience community* until after the plate tectonic revolution.

Conclusions

It is now established that the Earth's lithosphere is divided into a number of rigid *Plate Tectonics, Precambrian* in relative motion. Tracing these motions back in time shows that Gondwana, Laurasia, and Pangea did exist in the past, *vindicating Wegener's idea completely*.

Graben; Taphrogen

Definition

A continental rift (Gregory 1894; Quennell 1982, 1985) is a fault-bounded elongate trough under or near which the entire thickness of the lithosphere (► [“Lithosphere, Continental”](#) and ► [“Lithosphere, Mechanical Properties”](#)) has been reduced in extension during its formation. Just as old mountain ranges may no longer have any topographic expression because of tectonic and/or erosional events, some, especially old, rifts may no longer appear as troughs for the same reasons, but their original trough shape is recognized by their stratigraphically younger fills, or metamorphically lower grade of their down-dropped central blocks (► [“Sedimentary Basins”](#)).

Introduction

Rifts form one of the three main categories of lithospheric-scale structures resulting from differential motion of parts of the lithosphere. Lithospheric shortening creates orogens, simple shear creates keirogens, and stretching creates taphrogens that are collections of rifts (Fig. 1). However, at present only 20.5% of the active plate boundaries show normal convergence and 21% normal divergence. Some 8% show pure dextral strike-slip and some 6% pure sinistral strike-slip. The remaining 58.5% display some deviation from the three end-members, with relative motion vector angles to boundary strikes varying between 0° and 67° (Woodcock 1986). Plate boundaries must have shown a similar behavior in the past, so only about half of all the rifts a geologist may encounter is likely to show normal extension (► [“Plate Motions in Time: Inferences on Driving and Resisting Forces”](#) and ► [“Plates and Paleoreconstructions”](#)).

Continental Rifts, Fig. 1 A ternary diagram of strain showing the three lithospheric megastructure categories resulting from various strains

Rifts are important structures from the viewpoints of our understanding of the behavior of our planet and our exploitation of its resources. They record evidence of continental fragmentation in diverse tectonic settings including all three types of plate boundaries and in plate interiors (► [“Plate Motions in Time: Inferences on Driving and Resisting Forces”](#) and ► [“Plates and Paleoreconstructions”](#)). Also, at different stages of their evolution they present opportunities of studying the continental crust (and in extreme cases even the upper mantle) from its surficial sedimentary rocks down to the crust-mantle interface (► [“Lithosphere, Continental”](#)). Especially the lacustrine sedimentary sections of rifts are useful for studies on the past climates (e.g., Olsen and Kent 1999; Kravchinsky et al. 2003; Felton et al. 2007), and they have enabled geologists to refine stratigraphic correlations down to thousands of years as far back as in the early Mesozoic (e.g., Olsen and Kent 1999).

Rifts house important economic reserves such as hydrocarbons (the Sirt rift in Libya being the most productive with about 45 billion barrels of oil and 33 trillion cubic feet of gas; for the hydrocarbon potential of rifts, see: Harding 1983; MacKenzie and McKenzie 1983: a classic on hydrocarbon genesis in rifts; Ziegler 1994a; Lambiase 1995), hydrothermal and stratiform copper, copper-nickel, molybdenum, giant lead-zinc, and even uranium deposits (for metallogenesis in rifts, see Sawkins 1990). Most of the geothermal areas in the world are located in active rifts (e.g., Jaffé 1971, Fig. 1) (► [“Geothermal Heat Pumps”](#)). At present 1/5 of the entire fresh-water reserve of the Earth resides in a rift basin, namely, Lake Baykal. Rifts are thus significant not only for increasing our geological knowledge, but also for contributing to our well-being. It is perhaps of some interest in this context to remember that our genus and species were born in a rift, namely, in the East African.

For good overviews of rifts and rifting, see Burke and Dewey (1973), Burke and Wilson (1976), Coward et al.

(1987), McKenzie (1978 a “must” reading for understanding the evolution of rifts), Manspeizer (1988), Ziegler (1992, 1994b), Landon (1994), Şengör (1995), Şengör and Natal’in (2001: a detailed catalogue of the world’s rifts with tabulated summaries of origin and history and references), and Ring and Wernicke (2009). For the geology of some of the classic rift regions of the world, with increasing age, see: Africa as a whole: Kampunzu and Lubala (1991), Burke (1996), and Burke and Gunnell (2008). East Africa: Frostick et al. (1986), Frostick (1997: a good introduction for beginner), Schlüter (1997; this book has a bibliography of some 1300 items), Morley (1999; has an excellent collection of seismic sections). Basin-and-Range: Wernicke (1990), Beratan (1996), Faulds and Stewart (1998), Snow and Wernicke (2000), Dickinson (2002: best introduction for an outsider), and McQuarrie and Wernicke (2005; best kinematic reconstruction of any rift I know). Rio Grande rift, USA: Ingersoll (2001). The Upper Rhine rift: see the special issue on it in the *International Journal of Earth Sciences (Geologische Rundschau)*, v. 94 (2005); also: Hüttner (1991), Schumacher (2002), Rotstein et al. (2006). The Lake Baykal rift: Crane et al. (1991), Kuz’min et al. (2001), ten Brink and Taylor (2002), Kravchinsky et al. (2003). The West Siberian Basin: Surkov et al. (1994). The North Sea Basin with the North German (Lower Saxony) Basin: Blundell and Gibbs (1990), Evans et al. (2003; this lavishly illustrated and richly documented mammoth book makes all earlier publications on the subject either obsolete or redundant; also available as a two CD-ROM set), Wilson et al. (2004), Littke et al. (2008). The Mediterranean region: Durand et al. (1999), Corti et al. (2006; an excellent paper about a little-known rift cluster).

Willis (1936, 1–30) presents a good historical review of ideas pertaining to rifting. For some of the important early ideas on rifting, see Şengör (2018). For an excellent recent review of ideas and studies on the East African rifts, see Mohr (2009). For a history of uplift-related rift ideas, see Şengör

(2003). For a historical review of recent developments in our understanding of extensional tectonics, see Wernicke (2009). Quennell (1982, 1985) are anthologies of some historical papers on rift studies. They are not satisfactory, but are the only ones of their kind.

Rift, Graben, and Taphrogen

“Rift” and “graben” are two words used interchangeably in the international literature designating elongate troughs bounded by normal faults. However, not all such troughs are parts of structures that rupture, or even thin by rock creep, the entire lithosphere. Some normal-fault-bounded troughs result from sliding and stretching of surficial rocks over lubricating sedimentary horizons such as evaporites or shales. The normal-fault bounded basins that formed during a landslide associated with the 27 March 1964 Prince William Sound earthquake in Alaska or the similar troughs in the Canyonlands National Park in Utah formed by sliding and stretching the sedimentary section above the Upper Carboniferous evaporites are examples. Such structures have nothing to do with lithospheric stretching and thus they do not fit the definition of rift given above. Şengör (1995) therefore suggested that the word rift be confined to those structures that actually disrupt or otherwise (by creep) thin the lithosphere and graben be reserved for those that do not. His usage is what is recommended and followed in this entry. In rifts when the extension factor β , the ratio of extended width to unextended width (McKenzie 1978), goes beyond 3 the continental lithosphere generally ruptures completely and ocean generation begins by sea-floor spreading (Le Pichon and

Sibuet 1981) (► “Seafloor Spreading”) either by dyke injection or by cold extrusion of subcontinental mantle in the form of ultramafic “core complexes” as seen in such places as along the boundary between the Upper Penninic and the Lower Austroalpine units of the Alps (Bernoulli et al. 2003 and the references therein) or along the South Galicia Bank (Boillot et al. 1987). For obvious reasons, this cannot happen to grabens; however, much they may be extended.

Large regions of localized extension exist on our planet where many rifts and grabens occur together. It is inappropriate to call such regions simply rifts. It would be like calling whole orogens simply “thrusts.” These large regions of extension are the extensional counterparts of orogens (Figs. 1 and 7) and therefore it is appropriate to use for them the term “taphrogen” derived from Krenkel’s term “taphrogeny.”

General Properties of Rifts

Structure of Rifts

Figure 2 is an idealized and highly simplified block diagram of a rift. Rifts have two fundamental structural entities: a main hanging wall block and one or two footwall blocks depending on whether the rift is symmetric (as in Fig. 2) or asymmetric (see Fig. 3). In symmetric rifts, the extension represented by the rift is almost entirely localized between two master bounding normal (or oblique extensional) fault systems and it is these two systems that take up much of the extension, although the hanging wall block delimited by them is also intensely broken up by smaller normal faults with strikes largely parallel with those of the major bounding fault families (Fig. 4). The hanging wall is commonly dropped down

Continental Rifts, Fig. 2 A highly schematic block diagram of an “ideal” rift drawn to emphasize the main architectural elements of rifts. The straight marginal faults, for example, do not mean that all rifts must have straight faults or that they are single faults instead of fault families

Continental Rifts, Fig. 3 Some properties of symmetric and asymmetric rifts

because of crustal thinning affecting it and in the basin thus formed sediments accumulate whose thicknesses can be in excess of 15 km in large rifts such as the Dneper-Donetz rift in the Ukraine (Ulmishek et al. 1994), which is very close to the maximum possible thickness (17 km) of sediment accumulation on continental crust (Dewey 1982). Most rifts of average size, however, have sediment thicknesses ranging from 2 to 5 km. Individual rift lengths vary from about a 1000 km to 100 km and widths from about 150 to 10 km. Rift size is a function not only of the amount of extension, but also the thickness of the lithosphere it disrupts. The thicker the lithosphere, the wider the rift. In Fig. 5, the distribution of continental rifts on Earth is shown. In areas of thick lithosphere (e.g., in the North American craton, eastern Europe and Siberian craton), the rifts are very wide, whereas in areas of thin lithosphere such as the western USA or in the Aegean they are very narrow, in places less than 10 km wide.

The bounding faults of the rifts have long been thought to be listric (shovel-shaped), that is, flattening with depth, although studies on earthquakes have not supported this. Wherever precise hypocenter location is possible and where the earthquake has caused a surface rupture (► “[Earthquake, Focal Mechanism](#)”, ► “[Earthquakes and Crustal Deformation](#)”, and ► “[Earthquakes, Location Techniques](#)”), it is seen that the associated fault is planar down to depths of 8 to 10 km. Eyidogan and Jackson (1985) documented that the 28 March 1969 Demirci earthquake in western Turkey consists of two discrete subevents: one along a northerly dipping planar normal fault and another one on a horizontal surface north of, but at the same depth as, the hypocenter of the first one. The horizontal rupture is believed to be located in a

Continental Rifts, Fig. 4 A part of the eastern (“Gregory”) rift in Kenya showing the intense faulting of the down-dropped hanging wall block between the master fault families. Google Earth image

Continental Rifts, Fig. 5 Distribution of continental rifts in the world. (Updated from Şengör and Natal'in 2001)

region that deforms ductilely under long-term strain rates, but ruptures when that rate is suddenly increased as in an earthquake (Fig. 2). This suggests a kinked cross-section for the master fault. Such “kinked” faulting events may be the explanation of why hanging wall blocks in some rifts are so much more disrupted than the rift shoulders. In areas of thicker lithosphere, however, hypocenters along the master faults of rifts may be as deep as 30 km as exemplified by the 10 March 1989 Malawi earthquake in east Africa (Fig. 2; Jackson and Belknap 1993) (► “Seismicity, Intraplate”).

The straight fault hypothesis is difficult to generalize especially where the master fault families bounding rifts are strongly curved in map view such as those that created the Lake Tanganyika rift system (Burgess et al. 1988). It is possible that individual segments of large faults rupture as straight fractures, but eventually the entire fault acquires a listric geometry. This seems supported by the fact that in Lake Tanganyika, where the rift floor has deeply subsided, faulting within the hanging wall block is less intense (Burgess et al. 1988). This is incompatible with a major kink of the master fault at depth. Wernicke and Burchfiel (1982) pointed out that where numerous, parallel-striking planar normal faults have rotated in unison around horizontal axes, one listric fault at the head of the series is a kinematic necessity to allow the others to rotate.

Asymmetric rifts are said to “face” in the direction of the dip of their master faults (Fig. 3). Many major rifts are made up of half rifts that change their facing along the strike. In such cases, “transfer” or “accommodation zones” form along their boundaries that take the form of areas of complex oblique faulting and crustal block rotations (see especially the excellent discussions on transfer and accommodation zones in Faulds and Stewart 1998; also Derer et al. 2005). Smaller and shallower transfer faults, essentially tear faults disrupting the hanging wall block with complicated displacement histories, form where the hanging wall is differentially stretched along the strike of the rift (cf. Şengör 1987).

Rift shoulders are commonly uplifted. In symmetric rifts, both shoulders go up because of isostatic adjustment of the crustal wedges that are formed by the master faults dipping towards the rift (► “Isostasy”). Such uplift not only rotates the land surface on the shoulders away from the rift thus guiding much of the regional drainage in the same direction, but it rotates also the bounding normal faults (Buck 1988). Each increment of faulting further rotates the shoulder and further rotates the previously formed fault segment. In Fig. 3, in the case of a young asymmetric rift the fault is shown to be straight. As the rift ages and extension advances, the fault surface curves away from the rift as a result of incremental rotations and finally its oldest parts acquire a flat position,

possibly with “horses” of the hanging wall block stuck on it as “extensional allochthons” (Fig. 3). This seems to be the origin of many near-horizontal normal faults in areas of thin lithosphere and large amounts of extension such as the extensional metamorphic core complexes of the North American Cordillera (Armstrong 1982), or those of the Tethysides (Verdel et al. 2007), although the existence of “primary” low-angle normal faults is also known both from detailed field studies (e.g., Miller and John 1988) and from the seismicity (Eyidogan and Jackson 1985; Abers et al. 1997). The amount of extension in many rifts, especially those that are symmetric, does not go that far, however, and their bounding faults rarely dip less than 30°.

In places where intracontinental rifting along a narrow rift valley has advanced far, as, for example, along the Wonji Fault Belt in Ethiopia, it has been noted that faulting is driven by dyke injection below the brittle upper carapace of about 10 km thickness and that segments with active deformation at the surface correlate with those of active magmatism (Kendall et al. 2005; Casey et al. 2006).

Cloos (1939) believed that the shoulder uplift in symmetric rifts resulted from the original doming that had led to key-stone drop of the hanging wall block, but it was quickly realized that the observed angles of slope on crustal domes rarely exceed 1°, whereas to give rise to substantial rifts one needs about 10° dome slopes, which are excessive. Table 1 lists values of extension and shoulder uplift in some selected rifts. In none, except possibly in the Española Basin, is the shoulder uplift sufficient to cause the estimated amount of stretching.

Sedimentation in Rifts

Because rifts form elongate basins, they are ideal sediment receptacles. The type of sediment to be found in a rift varies according to the size and geometry of the rift, the climatic zone(s) in which it is located and its evolutionary history. Although most rifts are filled slowly by sedimentation in the sea, lakes, rivers and, in a subordinate degree, subaerially by wind, some are catastrophically invaded by the sea by breaching the barriers of sub-sea-level rift complexes (e.g., the Permian North Sea or the medial Cretaceous South Atlantic). In such cases, either vast evaporite deposits (as in the Aptian of the South Atlantic: Burke and Şengör 1988) or thick shales (as in the late Permian of the North sea: Evans et al. 2003) are laid down in rift troughs.

Subaerial rifts are normally fed by rivers that locally create lakes within them because of endorheic conditions. Near the fault-bounded shoulders, stream valleys are commonly short (as the crest of the shoulder often is also the water-divide) but the streams in them are energetic because of the steep slopes. They thus carry clastic sediments of a variety of sizes that are horizontally sorted in large alluvial fans at the feet of the fault-escarpments. Along these escarpments, many alluvial fans

Continental Rifts, Table 1 Amounts of extension and shoulder uplift at selected continental rifts

Name of rift	Amount extended (km)	Uplift of shoulder area (km)

^aBenkhelil et al. (1988) established at least 10 km of shortening during the following compression

form and coalesce and ongoing subsidence leads to the accumulation of large thicknesses of conglomerates, sandstones, and shales near the faulted rift margin(s). Because of rotation towards the fault plane of the basin floors, the sedimentary thicknesses systematically decrease away from rift shoulders towards rift median lines. Steep slopes and catastrophic rain in both tropical and desert climates frequently lead to slope failures resulting in landslides complicating the sedimentary record. Permanent or ephemeral lakes may occupy the middle parts of rift floors. Ephemeral lakes commonly occur in dry climates in the form of playas and deposit evaporites and clays that may interfinger with marginal alluvial fan deposits. Permanent and deep lakes are important sediment repositories in rifts. They may accumulate very thick sedimentary sections in them exhibiting complex facies dictated by the evolution of the geomorphology of the rift and its surroundings. Such lakes can be very deep (Lake Baykal in Siberia: with 1637 m the world’s deepest lake in addition to an 8 km rift sedimentary fill; Lake Tanganyika in East Africa: 1457 m, but with half the sediment thickness of Lake Baykal). They are

well-aerated in cold climates because the cold upper layers of the lake waters make convection and overturning possible (as in Lake Baykal), but they are stratified with anoxic deeps in hot regions because hot surface waters cannot sink and thus inhibit overturning (as in Tanganyika). As the anoxic conditions in Lake Tanganyika exemplify, deep rift lakes in hot climates may generate good hydrocarbon source rocks in reducing environments. This is corroborated by ancient rift fills that formed under similar conditions such as the Permian oil-bearing sequences in the Junggar and Turfan rift basins in Central Asia (e.g., Graham et al. 1990; Miao et al. 2006) or the organic-rich (up to 8% organic C) Triassic-Jurassic lacustrine sediments of the Newark-type rifts of the eastern United States (Manspeizer and Olsen 1981).

Rift valley floors are seldom level along the strike of the master bounding faults and this commonly induces longitudinal drainage in rifts. In fact most of world's major rivers flow in two kinds of valleys: those that are located in rift troughs or in depressions inherited from them and those that are placed in foreland basin troughs (cf. Audley-Charles et al. 1977). The Rhine in Europe, the Irrawady in Asia, flow along their almost entire lengths in active rift troughs. Along the western arm of the East African rift valleys, Lake Tanganyika receives (surface elevation at 773 m a.s.l.) the excess waters of Lake Kivu (at 1460 m) by means of the south flowing river Ruzizi that came into being only 10,600 years ago and may have stopped flowing between 8 and 6000 years ago (Felton et al. 2007) showing the sensitive dependence of rift sedimentation on the global climate. Farther north, just beyond Kivu, Lake Edward (at 912 m) is connected to Lake Albert (at 619 m) through the northerly flowing river Semliki. Lake Albert in turns feeds the Nile northwards via the river Albert Nile (White Nile or "Bahr al Jebel," that is, "the river of the mountain").

In the sedimentary record, the rift facies is commonly characterized by thick (2–15 km) clastic sequences with rapid thickness and facies changes both laterally and vertically. If the rifts are underwater and far from clastic sources, they may house carbonate and even siliceous sedimentary sections as illustrated by the Alpine Triassic-early Jurassic facies. There, a continuous passage from late Triassic shallow water carbonates via a horizon of extensional-faulting-related neptunian dykes filled with progressively deepening facies and finally covered entirely by radiolarian cherts indicates a stretching basin floor as it deepened. That no shoulder uplift is indicated by any unconformities suggests that the Alpine rift was asymmetric with a major south-dipping detachment and that the rocks on the hanging wall block never experienced normal-fault-related upheaval. If catastrophic marine invasion occurs, then sediments at once blanket the preexisting topography.

For good reviews of sedimentation in rifts, see Frostick et al. (1986), Lorenz (1988), Olsen and Schlische (1990), Leeder (1995), Şengör (1995), Beratan (1996), also the section entitled "Rift Basins" in Einsele (2000, 543–560).

Magmatism in Rifts

Rift magmatism is extremely variable, because the tectonic environments in which rifts form are so diverse (see below). Rifts that form above mantle plumes (► ["Mantle Plumes"](#)) in plate interiors away from plate boundaries may begin their activity with restricted volumes of alkalic basalts indicating limited partial melting of mantle material at depth and may evolve towards abundant tholeiitic effusions as the temperature at depth increases and more and more mantle rock is melted, as, for example, illustrated, by the evolution of the Afar plume in east Africa. Most geologists take alkalic to peralkalic magmatism as indication of extensional tectonics. The frequent association of nepheline syenites, kindred alkaline igneous rocks, and carbonatites ("alkalic rocks and carbonatites": ARC) with intracontinental rifts has been taken by Burke et al. (2003, 2008) to argue that deformed rocks of the same compositions ("deformed alkalic rocks and carbonatites": DARCs) that have been shown to characterize suture zones in regions in Asia, Europe, Africa and North America are nothing but ARC rocks that erupted into intracontinental rifts that became involved in a Wilson cycle of ocean opening and closing. This has been shown to form a powerful tool to map suture zones where other suture indicators such as ophiolites or subduction-related rocks may be missing. However, to think that rifts generate only alkalic magmatic rocks is clearly too simplistic. Those rifts that form along magmatic arc systems, for instance, inevitably have calc-alkalic magmas and those that form above recently thickened continental crust, may generate vast quantities of calc-alkalic andesitic/rhyolitic melts. Rifts forming in back-arc regions, such as those in the Aegean, contain volcanic rocks showing evidence for a metasomatized mantle beneath them (e.g., the so-called Kulaites, that is, hornblende basalts, in western Turkey: Richardson-Bunbury 1996). Large amounts of silica-rich magmatic rocks may be generated if mantle plumes manage to melt large quantities of continental crust while ascending or if fractional crystallization is allowed to proceed undisturbed (e.g., the Cretaceous tin granites in Nigeria or the Cainozoic granites in Scotland; see Wiart and Oppenheimer 2004 for an active example in Afar). Some rifts such as Tanganyika or Baykal are almost entirely devoid of magmatism, while others, such as the late Palaeozoic Oslo Rift, have floors made up entirely of magmatic rocks. Some Atlantic-type continental margins, which grew out of disrupted rifts, are called "volcanic," whereas others "non-volcanic," because they descended from rifts with similar magmatic characteristics.

It is naive to think that lithospheric extension generates only certain kinds of magmatic rocks without considering the tectonic environments that gave rise to the extension and in which the extension proceeds (► ["Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity"](#)). It is therefore imperative to look at the diversity of the environments which generate rifts.

For good reviews of magmatism in rifts, see Kampunzu and Lubala (1991), Kinnaird (1998), Ulrych et al. (1999), Burke et al. (2003, 2008), Wilson et al. (2004), Yirgou et al. (2006); also the special section on magmatism and extension in *Journal of Geophysical Research* 100 (1995).

Metamorphism in Rifts

Continental rifts are not commonly thought of as prime loci of metamorphic events, but five different kinds of metamorphic rocks do occur in them (► “[Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity](#)”). In increasing importance: (1) contact metamorphic rocks around rift-related magmatic rocks, (2) hydrothermal metamorphism around vents, (3) Buchan-type metamorphism due to rise of the asthenosphere below highly stretched rift floors and associated abundant intrusions, (4) burial metamorphism due to large sediment thicknesses, and (5) metamorphic rocks that form within the continental crust and are brought to surface by rifting.

There is little to say about the first kind of metamorphic rocks in rifts as they are no different from any other contact metamorphic rock. Hydrothermal metamorphism is important in many rifts, because of the high heat flow and the continuous opening of extensional fractures allowing hot waters to circulate (e.g., Crane et al. 1991). Buchan-type metamorphism in rifts recently attracted much attention as a result of the early metamorphic history of the Pyrenees (Wickham and Oxburgh 1985), Mouthumet and the Montagne Noir massifs in southern France during the late Palaeozoic (Şengör 2013). Rift-related metamorphism creating high-grade gneisses has been reported on the basis of condensed metamorphic zones and absence of associated plutonism also elsewhere (e.g., St-Onge and King 1987). Burial metamorphism is not common in rifts unless they accumulate very large thicknesses of sediment quickly, sufficient to raise the temperature and pressure conditions to initiate metamorphism. If we assume a normal geothermal gradient ($\sim 3^\circ\text{C}/100\text{ m}$; see ► “[Heat Flow, Continental](#)”), an accumulation of about 4 km of sediment would be sufficient to initiate metamorphism by raising the temperature beyond 120°C . Jackson (1987) argued, however, that because earthquake hypocenters in rifts are seldom deeper than 10 km, at least beyond that depth rocks must be metamorphic (the 600°C is a thermal limit above which earthquakes do not occur). In a few places, there are earthquakes down to 30 km, as in the east African Rift System. It is true however, that rift sediments are seldom metamorphosed beyond greenschist grade, because they are seldom stretched enough and seldom accumulate sufficient thicknesses of sediment to heat the rocks beyond 320°C . Smith (1976) pointed out, for example, that at the bottom of the about 16 km-thick Gulf Coast sediment pile, the temperature may be just about 320°C under 4 kb pressure. But this ignores both the radioactive heating of the pile (► “[Radiogenic Heat Production of Rocks](#)”) and raising the geotherm by stretching. However,

Continental Rifts, Fig. 6 Thermal regime of rifts with a simple geotherm. (a) Immediately after the stretching both the crust and the lithospheric mantle thin and isotherms become crowded under the rift increasing the heat flow in the rift. Although no particle in the rift basement will become any hotter. (b) After stretching ceases, isotherms begin to subside. (c) When the lithosphere “recovers” the rift will end up with more lithospheric mantle beneath it and will have a heavier substratum that will subside and pull its surroundings with it creating an “intracratonic basin” overlying the rift. This is called a “bovine head” cross-section because of its resemblance to a long horn ox. While the basin subsides, its margins will be elastically uplifted (solid line above c), but may relax visco-elastically in time (dotted line above c). Here the margins are shown only on one side for graphic convenience, but naturally the events will take place all around the basin

even when the crust is stretched, every particle in the stretched crust must cool, unless the rift trough is rapidly sedimented (Fig. 6; McKenzie 1978; Jackson 1987). I am unaware of any well-documented metamorphic terrane that formed as a consequence solely of rift burial.

By contrast, large normal faults of the kind shown for the advanced asymmetric rifts in Fig. 3 may pull up rocks from the lower continental crust that may have been metamorphosed even up to granulite facies as shown by many extensional metamorphic core complexes. But in this case the metamorphism is not *caused* by rifting, but it is *exposed* by rifting. In fact, as the rocks ascend in the footwall, they get retrograded, which is directly caused by rifting.

For metamorphism in rifts, see: Armstrong (1982), Wickham and Oxburgh (1985), Jackson (1987), Lister and Davis (1989), Block and Royden (1990), Verdel et al. (2007), and Şengör (2013).

Kinds of Rifts

A classification of rifts must serve to answer the questions: how many different sorts of environments lead to lithospheric extension and what kinds of rifts form in these environments? In essence one must specify where and how taphrogens commonly form. If taphrogeny stops before producing ocean, it causes subsidence and creates large basins (called “koilogens” by Spizaharsky and Borovikov 1966, pp. 113ff.) overlying taphrogens (Fig. 6; cf. McKenzie 1978; Şengör 1995). A comprehensive synthesis of various taphrogen types does not yet exist. Below is a restatement of Şengör’s (Şengör 1995; Şengör and Natal’in 2001) classification of types of rifts that make up the main elements of taphrogens. That classification is hierarchical and goes from pure geometry to dynamics (Fig. 8). Its hierarchical nature allows the environment and the path of formation of a given rift to be determined. For numerous examples of each of Şengör’s categories, see Şengör and Natal’in (2001). In this section, references already given in Şengör (1995) and in Şengör and Natal’in (2001) are not repeated.

Şengör’s classification has three different categories that do not completely overlap, namely *geometric*, *kinematic*, and *dynamic*. In the following, the three different categories are identified with their initials, that is, *g*, *k*, and *d*, respectively.

Geometric Classification of Rifts (See Figs. 7 and 8)

Rifts or groups of rifts forming individual taphrogenic units display five kinds of fundamental map patterns. From simplest to more complex, these are:

- g1) Solitary rifts:* Solitary rifts form small, fairly insignificant, and very rare taphrogens and are extremely difficult to ascertain in the geological record, because it is commonly hard to tell whether a given rift fragment is isolated or part of a larger taphrogen (for a comparable difficulty in shortening structures, imagine a big solitary fold or a large thrust fault!).
- g2) Rift stars:* Rift stars form when more than two rifts radiate away from a common center, building a roundish taphrogen. Rift stars are very common features of the structural repertoire of our planet today.
- g3) Rift chains:* When several rifts are aligned end-to-end along linear/arcuate belts of rifting, they form *rift chains*. The East African Rift System constitutes the best known active rift chain in the world. Solitary rifts or rift stars or combinations of these may be connected to form different kinds of rift chains (e.g., Fig. 5 rift chains a or b).
- g4) Rift clusters:* When several subparallel rifts occur in roughly equant areas, they are said to form a *rift cluster*. The two best-known active rift clusters in the world are the Basin-and-Range extensional area in North America and the Aegean Sea and the surrounding regions (see Fig. 5).
- g5) Rift nets:* Rift nets constitute a rare pattern, which comes about when rifts form a roughly checkered pattern as in the Proterozoic basement of the East European platform or in the late Mesozoic in central North Africa (cf. Şengör and

Continental Rifts, Fig. 7 The geometric classification of taphrogens. (After Şengör 1995)

Continental Rifts, Fig. 8 The classification of rifts and taphrogens. (After Şengör 1995)

Natal'in 2001). They resemble chocolate-bar boudinage, as seen in the Proterozoic basement of Eastern Europe (Fig. 5), and may have a similar origin, but more commonly rift nets form in complex and rapidly shifting stress environments in which dominant extension directions change fast. Many rift nets in fact may represent two superimposed rift clusters.

Kinematic Classification of Rifts (See Fig. 8)

Because rifts are ubiquitous in all stages of the Wilson Cycle of ocean opening and closing, the kinematic characteristics of the plate boundaries have been taken as a basis for classifying them according to the environment of the overall displacement and strain in which they form. There are three types of plate boundaries plus the plate interiors, to which four types of rift families correspond. In addition, incompatibilities arise around some unstable intracontinental triple junctions leading to complex rifting that should be treated separately from the other four classes, thus creating a fifth kinematic class, called "triple-junction rifts."

k1) Intraplate rifts: Rifts surrounded entirely by underformed lithosphere occupy this category. Such rifts are usually solitary, small, and rare (the difficulty in forming them is analogous to that forming a solitary fold or a nappe surrounded by entirely underformed terrain) and are not easy to identify in the geological history. The Lake George and Lake Champlain rifts in the northeastern United States are active examples (► "Seismicity, Intraplate").

k2) Rifts associated with divergent plate boundaries: These rifts result from plate separation along nascent extensional boundaries. All the Cainozoic rifts in east Africa belong here. This category of rifts may be further subdivided into two classes as follows:

k21) Rifts that form following an episode of doming: The divergent boundary along which rifts form is in this case preceded by an episode of lithospheric doming. The East African Rift Valleys are the best-known examples of such rifting (► "Isostasy, Thermal").

k22) Rifts that form with no pre-rift doming: In this case rifts form without a prelude of uplift, as is the case in the

Salton Trough and the Gulf of California. A good fossil example is the rifting of the Alpine Neo-Tethys in the earlier Mesozoic.

k3) *Rifts that form in association with conservative plate boundaries*: Conservative, that is, transform fault, boundaries are those along which neither extension nor shortening is required by the regional slip vectors. However, various reasons conspire to induce both extension and shortening to occur along considerable stretches of these boundaries. Rifts along conservative plate boundaries form in three different settings:

k31) *Transtensional conservative boundaries*: If a conservative boundary is opening up all along its length because of a component of extension, it is called *transtensional*. Many active rifts have a transtensional component and fossil examples of such rifts may be recognized largely through the structures they contain as shown by Olsen and Schlische (1990). Dewey (2002) gave an exhaustive analysis of the strain that develops in such rifts.

k32) *Pull-apart basins along conservative boundaries*: Major strike-slip faults commonly have bends along them that either facilitate (“releasing bends”) or obstruct (“restraining bends”) slip along them. Extensional basins form along the releasing bends, in which the magnitude of extension equals the magnitude of cumulative strike-slip offset along the strike-slip fault since the formation of the releasing bend. Such basins are called “pull-apart basins.” Crowell’s (1974) fault-wedge basins are nothing more than special cases of pull-apart basins.

k33) *Sphenochasms*: Not all basins created by secondary extension associated with strike-slip faults are pull-apart basins. Some represent tears caused by either an asperity or differential drag along the strike-slip fault in one of the fault walls, in which the amount of extension changes from a maximum along the fault to zero at the pole of opening of the tear-basin. S. W. Carey called such wedge-shaped rifts that open towards a major strike-slip fault *sphenochasms*.

k4) *Rifts that form in association with convergent plate boundaries*. A large family of rifts forms in association with convergent plate boundaries. In this group, a first-order subdivision is between rifts associated with subduction zones and rifts associated with continental collision, although this may artificially split some genetic groups, such as those rifts that presumably form because of the tension generated by excessive crustal thickening. The usefulness of the present grouping is that it enables a rapid overview of the presently active rift environments and comparison with ancient ones.

k41) *Rifts associated with subduction zones*: Environments of rifting associated with subduction zones

correspond to three different types of arc behavior, namely, extensional, neutral, and compressional arcs.

k411) *Rifts associated with extensional arcs*: An extensional arc generally splits along the magmatic axis (if such an axis is already in existence) forming a small rift chain. Such a situation is today known from both the Okinawa rift and the Izu-Bonin arc system. Such rifts commonly do not get preserved intact, both because of the complications of the tectonic evolution of arcs involving common changes of behavior and because of later collisions with other arcs or continents.

In extensional arcs, rifts also develop orthogonal to arc trend owing to the extension of the arc as it bows out in front of an expanding marginal basin (as, for instance, in Crete).

k412) *Rifts associated with neutral arcs*: Neutral arcs have neither shortening nor extension across them. Therefore, the only rifts that may form in neutral arcs are those associated with arc-parallel strike-slip faults, which may be classified in the same way as the rifts that form along conservative plate boundaries. More complex rift basins may originate along such arc-parallel strike-slip faults, if the sliver plate in the forearc area and its various pieces rotate about vertical axes.

Pull-apart basins in arcs are difficult to recognize, but the Sumatra Fault has several well-developed examples along it.

Sphenochasms along strike-slip faults in arcs are rarer still. Davis et al. (1978) have discussed two possible examples, the more recent of which may have created the “Columbia Embayment” by motion along the Straight Creek fault in the latest Cretaceous and the earliest Cainozoic.

k413) *Rifts associated with compressional arcs*: In compressional arcs crust commonly thickens and lithosphere thins, both by heating and by eventual delamination. The arc becomes shortened across, and elongated along, its trend. This elongation commonly generates rifts at high angles to the trend of the arc. Rifts on the Altiplano in the Andes are examples of such high-angle rifts.

k42) *Rifts associated with zones of continental collision*: Three different environments of rifting form associated with the collision of continents: (1) *Lines of extension* that radiate from points at which collision commences, (2) *Regions of extension* abutting against sutures, and (3) *Nodes of extension* in areas of complex deformation in fore- and hinterlands shattered by collisions. Impactogens (k421), rifts forming in intracontinental convergence belts (k422), and pack-ice-type rifts (k423) correspond with these three environments, respectively.

k5) *Triple Junction Rifts*: Triple junction rifts form at or near unstable intracontinental triple junctions, at which plate evolution dictates the generation of “holes” because continental lithosphere cannot be continuously subducted.

Dynamic (Genetic) Classification of Rifts (See Fig. 6)

Rifts are also classified according to the origin of forces (► “*Geodynamics*”) that lead to rifting. Şengör and Burke (1978) proposed that stresses which cause rifting may be imposed on the lithosphere directly by the mantle beneath it (cf. Şengör 2001) or they may result from two-dimensional plate evolution. Accordingly, they termed these two modes of rifting “active” and “passive.” Gans (1987) tried to replace these terms with “open-system” and “closed-system” rifting, respectively, which, however, did not find general acceptance.

d1) *Active rifting*: “Active rifting” is rifting caused by mantle upwelling (► “*Earth, Density Distribution*” and ► “*Mantle Convection*”) associated with plumes in the mantle (► “*Mantle Plumes*”). Two views have been advanced to explain the origin of the extension in domes rising above hot-spot jets: one ascribes the rifting to basal shear stresses induced by a spreading plume head beneath a dome. The other holds the potential energy of the rising dome responsible for driving the rifting. All of these factors probably do contribute to maintaining the active rifting process at its habitually slow pace of considerably less than 1 cm/a (► “*Geoid*”).

Plume-caused taprogens may be also termed deeply-rooted rifts and would be the extensional counterparts of subduction-related orogens (Fig. 9a, b). These can be contrasted to collisional orogens that have lost their subductive “anchors” and the passive rifts with no deep mantle connexions (Fig. 9c, d).

d2) *Passive rifting*: In the passive rifting mode, extension is caused by the two dimensional motions of the lithospheric plates and not by an autonomous interference from the mantle (Fig. 11d). In this mode of rifting, there is no prerifting doming associated with a hot-spot (Şengör and Burke 1978). Kinematic mechanisms reviewed above under the headings k22, k31, k32, k33, k411, k412, k413, k421, k422, k423, and k5 all may form rifts in a “passive rifting mode.”

There is only one kind of rift this classification does not consider: rifts that form by propagating from an already existing rift. Since propagation may take many forms, it might be sufficient to indicate such rifts with the notation d2 to indicate their passive mode of opening. The regional geologist may use Fig. 8 as a “flow chart” to follow the evolutionary histories of the various kinds of rift basins he encounters.

Continental Rifts, Fig. 9 Deeply rooted mega-structures ((a) subduction-controlled orogens, (b) mantle-plume controlled, i.e., active rifts) and rootless mega-structures ((c) collisional orogens, (d) plate motion-controlled, i.e., passive rifts)

Concluding Note

Although they constitute one of the three great continental structure types and have serious relevance to human well-being, rifts remain poorly known. This is largely because there are still important technological difficulties in studying them directly because of the large sediment thicknesses they contain and because their diversity is little appreciated. They are so ubiquitous in all tectonic environments that they tend to be overlooked in favor of other, rarer, structures that may appear more prominent. It is commonly not recognized that all kinds of structures such as magmatic arcs, collisional orogens, keirogens, intracratonic basins all have associated rifts and, consequently, people wishing to know about rifts tend not to concern themselves with them. A stereotypic rift that commonly bedevils textbooks is one that disrupts a craton

and has alkalic or peralkalic vulcanism with a thick, mainly nonmarine sedimentary fill, although there are many more rifts in the world than those with such characteristics. What is now needed in rift studies is a comprehensive synthesis that takes into account this diversity.

Dynamo: Process for generating electrical current and magnetic field by electromagnetic induction in a moving conducting medium

Geodynamo: Dynamo process in the fluid outer core that generates Earth's main magnetic field

Introduction

It has been firmly established that the geomagnetic field must be generated by a magnetohydrodynamic dynamo operating in the Earth's outer core. Thermal and compositional buoyancy forces drive a convective circulation of the liquid iron alloy. Assuming that a magnetic field is present, electrical currents are induced in the moving fluid. When the magnetic field associated with these currents has the strength and geometry that is suitable for the induction process and no external source for the field is required, this is called a self-sustained dynamo. To first approximation the Earth's core is a sphere with uniform electrical conductivity, in contrast to technical dynamos, where the currents are guided by a highly inhomogeneous distribution of electrical conductors. In the former case we speak of a homogeneous dynamo. From a theoretical point of view, homogeneous dynamos are more difficult to understand. Simple motions, such as differential rotation (as in an electrical generator), are unable to drive a homogeneous dynamo and flow patterns of a certain complexity are required. Until late into the twentieth century dynamo theory has been concerned mainly with the conceptual understanding of how, in principle, a magnetic field can be generated in such an environment. Starting with models by Glatzmaier and Roberts (1995), Kageyama and Sato (1995), and Kuang and Bloxham (1997), realistic self-consistent numerical simulations of the geodynamo became available and have been successful in reproducing many of the observed properties of the geomagnetic field. The more fundamental aspects of the geodynamo are discussed elsewhere (► “Geomagnetic Field, Theory”). Here, the progress in

understanding the geodynamo based on numerical modeling and comparing its results with specific properties of the geomagnetic field is addressed.

Dynamo Model Concept and Equations

Model Setup

In contrast to earlier kinematic dynamo models, where the flow is prescribed, modern geodynamo models aim at a fully self-consistent treatment of fluid flow and magnetic field generation in the Earth's outer core. There are some basic requirements for a realistic model: (i) The mechanism for driving flow by thermal or compositional buoyancy must be part of the model. (ii) Because an axisymmetric field cannot be generated by a dynamo (Cowling's theorem), the model must be fully three-dimensional. (iii) The model must be rotating, because Coriolis forces are important to generate a flow pattern that is conducive for the dynamo process. The basic setup of geodynamo models is that of a rotating spherical shell of outer radius r_o and inner radius r_i , filled with a fluid of uniform conductivity, which represents Earth's outer core (Fig. 1). For this system the coupled equations for convection-driven flow and electromagnetic induction are solved. A detailed account on fundamental aspects of convection in rotating spheres is given in Jones (2015) and modeling aspects and the commonly employed numerical schemes are discussed in Christensen and Wicht (2015).

Dynamo Equations

The relevant magnetohydrodynamic equations are usually written in nondimensional form. A possible scheme for

scaling the equations is to use the shell thickness $D = r_o - r_i$ as length scale, the viscous diffusion time D^2/ν as time scale (ν is kinematic viscosity), $(\rho\Omega/\sigma)^{1/2}$ for the scale of the magnetic field $\mathbf{B}$, and the imposed temperature contrast ΔT between inner and outer boundary for temperature T (ρ is density, σ electrical conductivity, and Ω rotation rate). The Navier-Stokes equation for the velocity $\mathbf{u}$, augmented by rotational and electromagnetic forces, is

$$E \left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right) + 2\hat{\mathbf{z}} \times \mathbf{u} + \nabla \Pi = E \nabla^2 \mathbf{u} + \frac{RaE}{Pr} \frac{\mathbf{r}}{r_o} T + \frac{1}{P_m} (\nabla \times \mathbf{B}) \times \mathbf{B}. \quad (1)$$

The terms on the left hand side describe in order the inertial force, the Coriolis force (with $\hat{\mathbf{z}}$ the unit vector parallel to the rotation axis), and the gradient of the non-hydrostatic pressure Π . The terms on the right hand side stand for viscous friction, thermal buoyancy forces, and the Lorentz force.

The magnetic induction equation, obtained from Maxwell's equations and Ohm's law for a moving incompressible conductor, is

$$\frac{\partial \mathbf{B}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{B} = (\mathbf{B} \cdot \nabla) \mathbf{u} + \frac{1}{P_m} \nabla^2 \mathbf{B}, \quad (2)$$

where the second term on the LHS describes magnetic field advection and the terms on the RHS magnetic field generation and diffusion, respectively. Magnetic diffusion is a consequence of the ohmic resistance that damps the electrical currents associated with the magnetic field.

The advection-diffusion equation for temperature is

$$\frac{\partial T}{\partial t} + \mathbf{u} \cdot \nabla T = \frac{1}{Pr} \nabla^2 T + \epsilon, \quad (3)$$

with a heat source term ϵ on the RHS. For compositional convection an equivalent equation holds where the concentration of light components replaces temperature. The set of equations is completed by the condition of incompressibility, which seems to be justified for Earth's core where density differences are moderate, and the condition that $\mathbf{B}$ is solenoidal:

$$\nabla \cdot \mathbf{u} = 0, \quad \nabla \cdot \mathbf{B} = 0. \quad (4)$$

The equations are complemented by boundary conditions for the velocity, usually $\mathbf{u} = 0$, fixed temperature or fixed heat flux at r_o and r_i , and a continuity condition for the magnetic field at r_o that links the field in the dynamo with an external potential field that decays with radius. Simple models assume the inner core to be insulating, but in many cases it is taken as an electrical conductor with the same conductivity as in the

Core Dynamo, Fig. 1 Columnar convection in a rotating spherical shell. The inner core tangent cylinder is shown by broken lines. Under Earth's core conditions the columns would be thinner and more numerous. (From Christensen et al. (2010). Copyright: Cambridge University Press)

outer core. It has been suggested that the finite conductivity of the inner core plays an important role for preventing frequent dipole reversals of the geodynamo, because a dipole reversal can only be completed successfully if the new polarity persists for the time scale of diffusive dipole decay in the inner core, $r_i^2/(\pi^2\lambda)$, which is several thousand years. However, this is contested by dynamo models that show little differences between simulations with a conducting or an insulating inner core.

Parameters

The four nondimensional control parameters in these equations are defined in Table 1. In dynamo models the values of most of these parameters fall short of their extreme values in the Earth's core. For practical reasons it is not possible to resolve the very small spatial structures that occur at realistic parameter values. The *Rayleigh number* Ra describes the ratio between buoyancy driving convection and retarding effects. In the core it is much larger than the critical value for the onset of convection, Ra_c , while models are more moderately supercritical (Table 1). The discrepancy is by at least eight orders of magnitude for the *Ekman number* E , the ratio of viscous forces to Coriolis forces. The very small core value of E indicates that viscous forces are negligible, except in very thin Ekman layers at the boundaries to the solid mantle and inner core. The *magnetic Prandtl number* Pm , the ratio of viscosity to magnetic diffusivity, is very small for liquid metals, but must be set to a value of order one to obtain a self-sustained dynamo in present models. Only the (hydrodynamic) *Prandtl number* Pr , the ratio of viscosity to thermal diffusivity, is of order one in the core and in dynamo models. In terms of physical parameters, the viscosity and the thermal diffusivity are far too large in the models, and in most cases, the rotation rate is too small.

Several dimensionless diagnostic numbers can be formed with the characteristic flow velocity U and magnetic field strength B in the dynamo (Table 1). The velocity in Earth's core can be estimated from the geomagnetic secular variation under the assumption that the magnetic flux at the core surface

is approximately frozen into the moving fluid (Alfvén's theorem), which is the case when the diffusion term in Eq. 2 can be neglected. In this case the variation of the radial magnetic field component B_r at the core-mantle boundary can be written

$$\partial B_r / \partial t + \nabla_h \cdot (\mathbf{u} B_r) = 0. \quad (5)$$

where the suffix h indicates the horizontal part of the divergence operator. Additional assumptions are needed to infer the velocity at the top of the core (below the Ekman layer) from the observed B_r and its time derivative, but the flow pattern obtained from these inversions are broadly similar and the characteristic velocity is approximately 0.5 mm/s (Holme 2015). The characteristic field strength inside Earth's core is probably in the range of a few mT (milliTesla), as will be discussed further below.

The most important diagnostic number is the *magnetic Reynolds number* Rm , which describes the ratio of magnetic advection and induction to magnetic diffusion. In order for induction effects in a dynamo to overcome the diffusive dissipation of magnetic field, it is expected that Rm must be larger than one. Practically, it turns out that self-sustained magnetic field generation occurs in geodynamo models when Rm exceeds approximately 40. Using $U \approx 0.5$ mm/s the magnetic Reynolds number is of order 1000, safely above the critical limit. Also, $Rm \gg 1$ is a condition for Eq. 5 to apply. Still, the value of Rm in the Earth's core is moderate and can be handled in direct numerical simulations. This contrasts with the much larger values of Rm in other cosmic dynamos, which requires that magnetic induction and diffusion effects at small unresolved scales are parameterized by applying concepts of the mean-field dynamo theory. The ability to solve for magnetic induction and diffusion in Earth's core directly without parameterizations is probably the main reason for the success of geodynamo models.

The (hydrodynamic) *Reynolds number* Re is much smaller in the models than it is in the core where it is of the order 10^9 , indicating a highly turbulent regime. Consequently, dynamo

models miss the small eddies that are expected to exist in the core. Viscosity kicks in only at length scales of some meters to suppress even smaller structures in the flow. However, the small eddies are unimportant for the magnetic induction process, because the magnetic diffusivity, which is $Pm^{-1} = 10^6$ times larger than the kinematic viscosity, homogenizes the magnetic field at scales of less than several tens of kilometers.

The *Elsasser number* Λ describes the ratio of Lorentz forces to Coriolis forces. In Earth's core both forces are assumed to be of leading order and to balance approximately in the so-called magnetostrophic state, which is often associated with an Elsasser number of order one. Many present dynamo models match this value of Λ .

The *Rossby number* Ro describes the ratio of inertial forces to the Coriolis force and is very small in the core. In models it is less than one, although larger than the core value. Instead of forming the Rossby number with the global length scale D , a more appropriate measure for the ratio of the two forces is obtained by using the characteristic length scale ℓ of the flow (local Rossby number Ro_ℓ). The value of Ro_ℓ is difficult to estimate for the core, but model values and the Earth value may be in better agreement than they are for Ro .

Flow in the Earth's core is thought to be in a MAC-balance, from **M**agnetic, **A**rchimedian, **C**oriolis, that is, these three forces balance to first order in Eq. 1 when putting pressure forces aside. Geodynamo models have been suspected to miss the correct force balance and to be controlled by viscous forces. However, a direct evaluation of force contributions shows that at least in simulations with an Ekman number smaller than 10^{-5} a MAC-balance is approached (Yadav et al. 2016). Simulations that have further pushed the viscosity (or E and Pm) to smaller values (Schaeffer et al. 2017) basically confirm the validity of many results that have been obtained with more viscous geodynamo models.

Energetics of the Geodynamo

Although the decay of radioactive isotopes in the core may contribute to some degree to the core heat flux, most of the buoyancy that drives convection in the outer core is associated with secular cooling. The sluggish convection in the mantle controls the heat flux through the core-mantle boundary in terms of its magnitude and its spatial distribution, which is expected to be rather heterogeneous.

Estimates put the heat flow at the core-mantle boundary into the range of 7–17 TW (Nimmo 2015). For thermal convection to occur, the temperature gradient must reach or exceed the adiabatic gradient. Because iron is a comparatively good conductor 10–15 TW can be transported by thermal conduction along an adiabatic gradient. This fraction of the heat flux is lost for driving the dynamo. It is possible that the

top of the core is thermally stably stratified. A consequence of core cooling is the slow growth of the solid inner core by freezing iron on its outer boundary. The associated latent heat release balances roughly one half of the heat loss from the core and renders the deep fluid core thermally unstable even if the top layer is not. The relative depletion of light alloying elements in the solid core is balanced by an enrichment in the residual fluid above the growing inner core, which drives compositional convection. Estimates for the work done by thermal and compositional buoyancy forces are in the range 0.8–5 TW (Nimmo 2015). Compositional buoyancy contributes roughly two-thirds to it. This energy flux is available to generate magnetic field and balance the associated ohmic dissipation. Viscous dissipation is usually assumed to play a minor role in the core.

Earth has a global magnetic field since at least 3.5 Gyr. At times before the inner core nucleated, estimated to have occurred 0.5–1.5 Gyr ago, only thermal convection could have driven the geodynamo. If the present core heat flux is less than the flux that can be conducted along an adiabat, it must have been significantly higher prior to inner core nucleation when compositional driving had been unavailable. A possible alternative is the exsolution of mantle components that had been dissolved in iron at very high temperatures during the Earth's formation. This would drive a form of compositional convection that is independent of the existence of an inner core.

Flow Pattern and Dynamo Mechanism

The pattern of flow is strongly controlled by the Coriolis force. It is different for the regions inside and outside the *inner core tangent cylinder*. This is an imaginary cylinder aligned with the rotation axis and touching the inner core at the equator, which is shown by broken lines in Fig. 1.

Flow Outside Tangent Cylinder

Outside the tangent cylinder, the flow is organized in convection columns aligned with the vector of rotation, with the flow encircling the column axis (Fig. 1). Superimposed is a circulation along the column axis that is directed toward the equatorial plane in columns with a cyclonic sense of rotation and away from the equator in anticyclonic columns. This results in helical flow, in which particles move on corkscrew-like trajectories. The helicity, $H = \mathbf{u} \cdot (\nabla \times \mathbf{u})$, is coherently negative in the northern hemisphere and positive in the southern hemisphere. Such helical flow is the basis for the α -effect, which can convert an axisymmetric toroidal field into an axisymmetric poloidal field, or vice versa, through intermediate steps involving non-axisymmetric small-scale fields (Moffatt 1978). Because purely axisymmetric fields cannot be maintained by a dynamo, this mechanism plays an important

role in the understanding of the dynamo process. The α -effect has been introduced in the context of mean-field dynamo theory, where it describes the induction effects of small unresolved flow scales. In geodynamo models and probably to some extent in the Earth's core it is due to fairly large-scaled convection columns (Busse 1975). The models suggest that the axisymmetric toroidal field in the Earth's core (which is invisible from the outside) consists of a torus of westward directed field north of the equatorial plane and eastward field south of the equatorial plane. The helical columnar flow converts this to a dipolar poloidal field whose field lines can leave the core (Fig. 2). In some dynamo models the toroidal magnetic field is regenerated by the same “macroscopic” α -effect from the poloidal magnetic field (α^2 dynamo, Olson et al. 1999). In other geodynamo models the shearing of poloidal field lines by differential rotation, the Ω -effect, has been found to play an important role for toroidal field generation ($\alpha\Omega$ -dynamo), but essentially all models confirm that the helical columnar convection produces the dipolar poloidal field component. Although at low Ekman number and high Rayleigh number the simple columns give way to a more complex and turbulent pattern, the vortices are still elongated in the direction of the rotation axis and retain statistically a coherent helicity in each hemisphere.

Core Dynamo, Fig. 2 Bundle of magnetic field lines in a simple geodynamo model ($E = 10^{-3}$, $Ra/Ra_c = 1.8$, $Pm = 5$, $Pr = 1$). The yellow blobs are anticyclonic vortices. Strong inward magnetic flux is shown in blue on the outer core boundary and outward flux in red. The NS-running part of the field lines represents poloidal magnetic field and the EW-directed segments form the axisymmetric toroidal magnetic field, which consists of two bundles of opposite directions in the two hemispheres. The same field structure repeats periodically in longitude. (Courtesy of Julien Aubert)

Strong concentrations of magnetic flux in the present geomagnetic field centered below North America and Siberia, which have counterparts at the same longitudes in the southern hemisphere, are interpreted as evidence for the presence of convection columns in the fluid core (Gubbins and Bloxham 1987) (Fig. 3a). The convergence at the core-mantle boundary associated with the equatorward flow in the axis of cyclonic columns (Fig. 1) concentrates the poloidal magnetic field lines into these flux lobes, assuming that the frozen flux assumption is approximately valid. In simple models, such as that in Fig. 2, the flux lobes are associated with a single columnar vortex. Dynamo models at lower Ekman number and strongly supercritical Rayleigh number show similar high-latitude flux lobes in their magnetic fields when they are low-pass filtered to the resolution of the geomagnetic core

Core Dynamo, Fig. 3 Radial magnetic field at the core-mantle boundary, red (full lines) inward and blue (broken lines) outward. (a) Geomagnetic field in 2010. (b) Dynamo model with dominant dipole contribution ($E = 10^{-5}$, $Pm = 0.8$, $Pr = 1$, $Ra/Ra_c = 114$). (c) Multipolar dynamo model ($E = 10^{-5}$, $Pm = 0.5$, $Pr = 1$, $Ra/Ra_c = 161$). The model magnetic fields are low-pass filtered to the resolution of the geomagnetic field

field, roughly up to spherical harmonic degree 13 (e.g., Fig. 3b). In this case, and probably in the Earth's core, the large-scale magnetic flux concentrations are due to the superposition of strong but complex and smaller-scaled magnetic field structures, each associated with a separate convection column.

Flow Inside Tangent Cylinder

In the polar regions inside the tangent cylinder, many dynamo models show an upwelling plume at or near the rotation axis. Because of the action of Coriolis forces, the plume is associated with an eastward vortex motion near the inner core and by westward vortex motion near the core-mantle boundary, which is called a thermal wind circulation. A westward vortex motion in the polar cap region at the top of the core has also been inferred from the observed geomagnetic secular variation (Hulot et al. 2002). A polar plume is associated with flow that diverges away from the rotation axis below the core surface, which disperses poloidal magnetic field lines. This is seen in many geodynamo models (e.g., Fig. 3b) and can explain the weak magnetic flux in the north polar region of the core (Fig. 3a). It has been suggested that the solid inner core couples electromagnetically to the eastward vortex motion of the overlying fluid, which leads to a superrotation of the inner core with respect to the mantle and crust. While perfect coupling to the outer core flow would lead to superrotation rates in excess of a degree per year (Glatzmaier and Roberts 1996), gravitational coupling between the inner core and the mantle can slow down the rate. Seismological evidence indicates a superrotation at a fraction of a degree per year.

Field Properties

Field Strength Inside the Core

How strong is the magnetic field inside Earth's core? Observations allow to constrain the strength of the poloidal field at the core-mantle boundary, which is presently 0.26 mT for the dipole field alone and 0.39 mT in spherical harmonic degrees from 1 to 13. It is not known how much the small unresolved length scale add to the field at the top of the core, but possibly they double this value. Inside Earth's core the poloidal field is expected to be stronger than at the outer boundary and the toroidal component also contributes. Suggestions that the toroidal field, if generated by an intense Ω -effect, could be much stronger than the poloidal field are not supported by geodynamo simulations. In most of them the magnetic energy is equipartitioned between the two field components. The dynamo models suggest that the characteristic field strength inside the dynamo is around 5–15 times the dipole field strength on the outer boundary, which would put it into the range of 1–4 mT.

The field strength inside Earth's core can be probed directly by the observation of torsional waves and oscillations. To the extent that viscous and inertial forces are negligible, the azimuthal Lorentz force integrated over the surface of cylinders that are aligned with the rotation axis (geostrophic cylinders) must vanish in the so-called Taylor state. Perturbations of the Taylor state will result in torsional oscillations or torsional waves, consisting of an oscillatory differential rotation between the geostrophic cylinders. Magnetic field lines that permeate adjacent cylinders act like elastic strings and provide a restoring force when the cylinders are displaced relative to each other. The frequency of torsional eigenmodes and the wavespeed of traveling waves are directly related to the *rms* strength of the field component B_s in the cylindrically radial direction. Some component of the large-scale flow in the core, which has been inferred from secular variation using Eq. 5, can be interpreted as a torsional wave that recurs every 6 years. This is in good agreement with a signal in the length-of-day variation at this period, that is, a change of the rotation rate of the solid part of the Earth caused by angular momentum exchange between core and mantle. From the time needed by the torsional wave to traverse the fluid core, approximately 4 years, a mean value of B_s in the range 2–3 mT has been deduced (Gillet et al. 2010).

Scaling Laws

An important question is what controls the magnetic field strength of the geodynamo and of planetary dynamos in general. It has been suggested that because of the requirement for a magnetostrophic state, the magnetic field inside Earth's core is driven toward a value that makes the Elsasser number (Table 1) to be of order one, that is,

$$B \propto (2\rho\Omega/\sigma)^{1/2}. \quad (6)$$

This results in $B \approx 2$ mT, in good agreement with the above estimates. A different line of argument is based on the power available to balance ohmic dissipation. With some assumptions on how the length scale of the magnetic field in the core depends on the vigor of convection, this leads to

$$B \propto \mu_o^{1/2} \rho^{1/6} P^{1/3}, \quad (7)$$

where $P = W/(4\pi r_o^2)$ stands for the power per unit area of the core surface. With the current estimates for W Eq. 7 results in a similar value of the field strength as the Elsasser number rule. However, the two scaling rules are radically different; in Eq. 6 the field strength is independent of the energy flux and in Eq. 7 it does not depend on rotation rate or electrical conductivity. Sets of dynamo simulations that cover a substantial range in these properties, or their counterparts in terms of the nondimensional control parameters, support the power-

based scaling law (Eq. 7). Furthermore, they show no significant dependence of the field strength on the viscosity. This may indicate that although current dynamo simulations are far too viscous (too high Ekman number), the viscosity is sufficiently low to not play a dominant role. The validity of the power-based scaling rule is also supported by the finding that it gives the right order of magnitude of the field strength for various convection-driven dynamos in rapidly rotating cosmic objects including Earth, Jupiter, and low-mass stars. A detailed discussion of dynamo scaling laws is given in Christensen (2010).

Magnetic Field Geometry

While the rotation rate seems to have little influence on the field strength inside dynamo models, it probably controls the magnetic field morphology. In some geodynamo models the magnetic field on the outer boundary resembles Earth's field at the core-mantle boundary (Fig. 3a, b) in terms of a dominant axial dipole and also of structures associated with multipole contributions. In other dynamo models the dipole contribution is weak. In some cases the field is dominated by the axial quadrupole or is restricted to one hemisphere, but in most cases it is irregular with contributions from a broad spectrum of multipole components without a pronounced dominance of a particular mode (Fig. 3c). The selection of the field geometry was found to depend on the (local) Rossby number. At low values (rapid rotation and moderate flow velocities) dynamos are dipolar, whereas for high values (slower rotation and fast flow) they tend to be multipolar. In addition boundary conditions and the mode of driving convection, that is, either by secular cooling of the fluid core or by the latent heat and light element flux from the growing solid inner core, can play a role. The driving mode has changed over geological time. Before the Earth's inner core nucleated 0.5–1.5 Gyr ago the dynamo has probably been driven more weakly than today by secular cooling alone, whereas thereafter the buoyancy source is mainly located at the inner core boundary. However, dynamo simulations for the different scenarios (Aubert et al. 2009) suggest that neither the geometry of the magnetic field nor its strength has changed very strongly. This is in accord with the lack of paleomagnetic evidence for drastic changes in the geomagnetic field since the Archean.

Secular Variation

Time Scales

The characteristic time scale of secular variation can be defined by the square root of the power of the magnetic field over the power in the time derivative of the field. This can be done separately for each harmonic degree n . The time scales decrease with increasing n . Aside from this scale dependence,

the secular variation time has been found in dynamo models to vary with the inverse of the magnetic Reynolds number (Christensen and Tilgner 2004), as would be expected if most of the secular variation is caused by the frozen-flux advection of magnetic field. Using the observed secular variation time scales to estimate the magnetic Reynolds number (or flow velocity) in the core gives essentially the same result, $Rm \approx 1000$, as the more complex inversion of the secular variation for the core flow.

Advection vs. Diffusion of Field

The westward drift of magnetic field structures is a long-standing issue. Some dynamo models show a persistent and global westward drift, whereas others do not. Over the past 400 years magnetic field structure have systematically migrated westward flow in the Atlantic hemisphere, but not in the Pacific hemisphere, where the amplitude of secular variation is generally weaker. Dynamo models support the notion that such hemispherical dichotomy can be caused by coupling between the mantle and the core, in particular by the heterogeneity of the core heat flow caused by lower mantle thermal structure.

While much of the geomagnetic secular variation can be attributed to frozen-flux advection in a large-scale circulation, magnetic diffusion must play some role, in particular diffusion in the radial direction. It has been suggested that intense flux spots of both polarities, which are found in the geomagnetic field at low latitudes under Africa and the Atlantic (Fig. 3a), have been formed by the expulsion of toroidal magnetic flux bundles through the core surface Bloxham (1986), somewhat analogous to the formation of sunspots. Because the toroidal field is confined to the core, the emergence of such spots necessarily involves diffusion, whereas their migration can be caused by frozen flux advection. Some geodynamo simulations support such origin of equatorial flux spots. In these simulations the columnar convection acts on a pair of toroidal flux bundles with opposite polarities and produces (anti)symmetric pairs of spots north and south of the equator. However, the geomagnetic low-latitude field pattern conforms at best marginally with this picture. An alternative explanation to the concept of field expulsion by convective columns and migration due to a large-scale westward flow is that propagating hydromagnetic waves in the core create a periodic pattern of upwelling and downwelling that produces the belt of wave-train-like magnetic field structures in the low-latitude Atlantic hemisphere.

Magnetic Field Reversals

Several dynamo simulations show stochastic dipole reversals. Often the details resemble remarkably well what is known from the paleomagnetic record about geomagnetic reversals

Core Dynamo, Fig. 4 Time series of dipole tilt, true dipole moment (TRM) and dipole strength relative to total field strength (RDS) from a numerical dynamo simulation (Wicht 2005). (Copyright Blackwell)

(e.g., Wicht et al. 2009). They are rather short events that interrupt long periods of stable polarity. Aside from complete reversals also excursions (aborted reversals) occur. During a reversal the magnetic field is weak and not dipole-dominated (Fig. 4). Most model studies of reversal behavior have been performed with simple dynamo models at rather high values of the Ekman number, because long simulation times are needed to capture a fair number of these events. Reversing dipolar dynamos are typically found in a parameter regime between that of stable dipolar dynamos and of multipolar dynamos. Driving convection more strongly for otherwise identical conditions leads to very frequent and erratic dipole reversals that have little significance because the dipole is hardly ever dominating the magnetic field. Lowering the Prandtl number has the same effect, suggesting that strengthening the nonlinear inertial forces relative to the Coriolis force favors non-dipolar dynamo. Reducing the convective driving or increasing the Prandtl number results in strong dipolar fields that rarely or never reverse. In addition, boundary conditions affect the reversal frequency. In particular, it has been shown that the pattern of heat flux at the core-mantle boundary, which is controlled by the thermal state of the lowermost mantle and varies on the long time scale of mantle convection, has a strong influence on the occurrence of reversals. This supports the assumption that the drastic secular change in the reversal rate over the past 200 Myr, which is observed in the paleomagnetic record, is caused by changes in the amplitude and pattern of core heat flow associated with a reorganization of mantle convection, such as formation and fading of superplumes. Although model studies have led to a number of suggestions concerning the cause for individual reversals, for example by the formation of strong new plumes in the core, so far no generally accepted concept for the reversal mechanism has emerged.

Summary

Helical convection columns outside the inner core tangent cylinder region play an essential role for our present understanding of the geodynamo. Theory and numerical simulations suggest that they are a fundamental element of the circulation in the outer core and that they play a key role for the generation of the Earth's dipole-dominated magnetic field. Certain details of the magnetic field structure at the core-mantle boundary are explained by such columns. Somewhat less certain, but supported by several lines of evidence, is the notion of rising plumes in the tangent cylinder near the rotation axis that are associated with weak magnetic field and westward vortex flow in the polar regions at the core-mantle boundary. Much of our current understanding is based on numerical dynamo models that are far too viscous compared to the core. Even if models that use actual core values of the viscosity are out of reach, recent simulations have lowered the viscosity to an extent that was previously numerically unfeasible. They suggest that many of the basic findings are not compromised by unrealistic viscosity values. Modeling supports the notion that the magnetic field strength is controlled by the available power that drives the dynamo. Several dynamo models show dipole reversals that resemble in many respects geomagnetic reversals, but a full understanding of what causes reversals or controls the frequency of geomagnetic reversals is missing.

Core-Mantle Coupling

Paul H. Roberts¹ and Jonathan M. Aurnou²

¹Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA, USA

²Department of Earth and Space Sciences, University of California, Los Angeles, CA, USA

Definition, Scope, and Aims

The Earth is not a perfect timekeeper, and the spectrum of the variations in the mantle's angular velocity $\hat{\Omega}$ spans a wide range of frequencies. Of particular interest here are the comparatively large amplitude decadal and semidecadal variations in which changes in length of day, P , of up to 2 ms occur. These would not be explained even if the global circulations of the atmosphere and oceans could be reversed. This is confirmed by a more detailed argument given in our recent review (Roberts and Aurnou 2012), which will be referred to here as “RA12.”

The origin of these length of day (LOD) variations must be sought in the Earth's core, and Fig. 1 suggests that the task is not an easy one. Fig. 1b shows dP/dt , derived by differentiating smoothed LOD data from the last half century, with atmospheric, oceanic, and tidal signals removed; semi-decadal time variations are clearly seen with a period τ_{LOD} of about 6 years (e.g., Abarca del Rio et al. 2000). Figure 1c shows the implied $\hat{\Gamma}_z$ as a function of time t , where $\hat{\Gamma}_z$ is the component parallel to the polar axis O_z of the torque $\hat{\Gamma}$ exerted by the core on the mantle. This shows that $\hat{\Gamma}_z$ of nearly 10^{18} Nm is generated. We shall call this the “target torque” and seek its origin.

In addition, to the semi-decadal oscillations, larger variations seem to exist having longer periods, one of which is estimated to have a roughly 60 year period (e.g., Roberts et al. 2007). This time scale is reminiscent of the geomagnetic secular variation, and it is natural to seek a connection between them (e.g., Braginsky 1970; Gillet et al. 2010). Figure 1c supports this quest. It shows the LOD data (Gross 2001; Holme and de Viron 2005) plotted against the estimated LOD variations inferred from the core flow models of Jackson (1997) that are based on inversion of geomagnetic secular variation data. The qualitative agreement implies that the

variations in LOD are due to core-mantle angular momentum exchange associated with magnetohydrodynamic (MHD) processes in the core.

This review will focus on variations in LOD, i.e., changes in $\Omega_z (\approx \Omega)$. Precession and nutation of the Earth's axis, which describe variations in Ω_x and Ω_y , are also phenomena that cannot be satisfactorily explained without invoking core-mantle torques, but they are beyond the scope of this review. It will become clear that torques on the Solid Inner Core (SIC) are also of interest. Variables in the SIC will be distinguished by a tilde ($\sim$) and those in the mantle by a hat ($\hat{\cdot}$). Except when making general statements, unadorned letters will refer to variables in the Fluid Outer Core (FOC).

The Four Coupling Processes

The torque on the mantle about the geocenter O is

$$\hat{\Gamma} = \oint_S \mathbf{r} \times \hat{\mathbf{T}} dA, \quad \text{where } \hat{T}_i = -\hat{S}_{ij} n_j, \quad (1a, b)$$

sometimes called the “surface traction,” is the stress associated with the normal and $\hat{S}_{ij}$ is the total stress tensor; $\mathbf{r} = r\mathbf{1}_r$ is the radius vector from O, $r = |\mathbf{r}|$. The minus sign in Eq. 1b arises because our unit normal, $\mathbf{n}$, to $\hat{\mathbf{S}}$, the Core Mantle Boundary (CMB), points into the mantle. The axial torque, i.e., the component of $\hat{\Gamma}$ along the rotation axis Oz, is

$$\hat{\Gamma}_z = - \oint_S s \hat{S}_{\phi n} dA, \quad (1c)$$

where s is distance from the z -axis. For the torque on the SIC, we have similarly

$$\begin{aligned} \tilde{\Gamma} &= \oint_S \mathbf{r} \times \tilde{\mathbf{T}} dA, & \tilde{T}_i &= \tilde{S}_{ij} n_j, \\ \tilde{\Gamma}_z &= \oint_S s \tilde{S}_{\phi n} dA; \end{aligned} \quad (1d, e, f)$$

there is no minus sign in Eq. 1e, f because our unit normal, $\mathbf{n}$, to the Inner Core Boundary (ICB) points out of the SIC.

Core-Mantle Coupling, Fig. 1 (a) LOD time series data from Holme and de Viron (2005) and Gross (2001) compared with LOD model from the “smooth” core flow inversion of Jackson (1997). The time series include the variation due to lunar tidal drag. (b) Temporal derivative, dP/dt , of the smoothed time series data of Holme and de Viron (2005), where P is the

length of day. (c) The implied axial torque, $\hat{\Gamma}_z = -(2\pi\hat{C}/P^2) dP/dt$, on the mantle, where $\hat{C}$ is the axial moment of inertia of the mantle. The LOD in panel (a) is arbitrary to within an additive constant, chosen here to obtain agreement at 1972.5 with Gross (2001)

Equation 1a tacitly assumes that the core alone exerts a torque on the mantle; sources of torque from outside the Earth are ignored, and therefore

$$\begin{aligned}\mathbf{\Gamma} + \hat{\mathbf{\Gamma}} + \tilde{\mathbf{\Gamma}} &= \mathbf{0}, \\ \mathbf{M} + \hat{\mathbf{M}} + \tilde{\mathbf{M}} &= \text{constant},\end{aligned}\quad (1g, h)$$

where $\mathbf{\Gamma}$ is the torque on the FOC; $\mathbf{M}$, $\hat{\mathbf{M}}$ and $\tilde{\mathbf{M}}$ are the corresponding angular momenta. Eq. 1g implies that, if one of the three torques changes, so do one or two of the others, in the opposite sense. The system is, in this respect, self-regulating. We shall treat the mantle and SIC as rigid bodies below.

Stress is exerted on the CMB in four ways: through viscosity, topography, gravity, and magnetic field, and there are correspondingly four parts to each of S_{ij} , $\mathbf{T}$ and $\mathbf{\Gamma}$, e.g., $\hat{\mathbf{\Gamma}} = \hat{\mathbf{\Gamma}}^V + \hat{\mathbf{\Gamma}}^T + \hat{\mathbf{\Gamma}}^G + \hat{\mathbf{\Gamma}}^M$. The topographic and gravitational torques depend on the non-sphericity of $\hat{\mathbf{S}}$ and $\tilde{\mathbf{S}}$. For the others, negligible error is made by replacing the CMB and ICB by spheres, $\hat{\mathbf{S}}$, and $\tilde{\mathbf{S}}$, of radii r_o and r_i . The torques will be estimated below.

The Viscous Torque

Assuming uniform fluid density, ρ , and kinematic viscosity, ν , the part of the viscous stress tensor, $\hat{S}_{ij}^V$, responsible for $\hat{T}_i^V$ is $\rho\nu\nabla_j V_i$, i.e., $\hat{\mathbf{T}}^V = -\rho\nu(\mathbf{n} \cdot \nabla)\mathbf{V} \approx -\rho\nu\partial_r\mathbf{V}$ so that, by Eq. 1a, c,

$$\begin{aligned}\hat{\mathbf{\Gamma}}^V &= -\rho\nu \oint_{\hat{\mathbf{S}}} \mathbf{r} \times \partial_r \mathbf{V} \, dA, \\ \hat{\Gamma}_z^V &= -\rho\nu \oint_{\hat{\mathbf{S}}} s \partial_r V_\phi \, dA.\end{aligned}\quad (2a, b)$$

These torques involve only the radial gradient of the fluid velocity, $\mathbf{V}$. This tends to drag the mantle in the direction of the subsurface flow.

The viscosity of core fluid is hard to estimate. First principles calculations (de Wijs et al. 1998; Dobson et al. 2000; Vočadlo et al. 2000) suggest that ν at the CMB is within a factor of 3 of $10^{-6} \text{ m}^2 \text{ s}^{-1}$. Suppose the viscous stress transfers momentum between the core and mantle over a length scale $d_v = E^{1/2} r_o \sim 0.2 \text{ m}$, which is the thickness of the laminar Ekman boundary layer. Here

$$E = \nu / \Omega \mathcal{L}^2 \quad (2c)$$

is the Ekman number ($\approx 3 \times 10^{-15}$), which quantifies the ratio of the viscous and Coriolis forces; $\mathcal{L}$ is a characteristic scale of motion outside the boundary layer, for which we take $\mathcal{L} = r_o$. Assuming velocities of order $\mathcal{V} \approx 10^{-4} \text{ m s}^{-1}$ (e.g., Jackson

1997), the surface fraction, $\hat{T}^V \approx \rho\nu\mathcal{V}/d_v$, is about 10^{-5} N m^{-2} , implying that $\hat{\mathbf{\Gamma}}^V \approx 5 \times 10^{14} \text{ Nm}$.

In a highly turbulent medium such as the FOC, small scale motions transport macroscale quantities, such as angular momentum, far more effectively than molecular diffusion. When these scales are too small to be resolved by numerical computations, they are termed “sub-grid scales.” Their effect must then be included in some other way. Appeal is often made to an analogy with molecular diffusion. Molecular transport depends on the molecular mean-free-path, ℓ , and the rms molecular speed, u . Simple dynamical arguments show that the molecular diffusivity, ν , for momentum is of order $u\ell$. The analogy pictures small scale eddies replacing molecules as the transporters of macroscale momentum. The correlation length, l_{cor} , of the turbulence replaces ℓ and the rms turbulent velocity, v , replaces u . The transport of macroscale momentum is then governed by a kinematic “turbulent viscosity” $\nu_T \approx vl_{\text{cor}}$, which greatly exceeds ν . We use $v = 10^{-4} \text{ m s}^{-1}$ for the velocity scale. The length scale is harder to estimate. Here we take $l_{\text{cor}} \sim E^{1/3} r_o \approx 100 \text{ m}$, which is based upon the characteristic length scale for finite amplitude rapidly rotating convection (e.g., Stellmach and Hansen 2004; Sprague et al. 2006). This gives $\nu_T \approx 10^{-2} \text{ m}^2 \text{ s}^{-1}$. Though it is strictly inconsistent to use v and l_{cor} when estimating the shear on the resolved scales, an upper bound on the turbulent traction follows from doing so: $\hat{T}^V \approx \rho\nu_T v / l_{\text{cor}} \approx \rho(vl_{\text{cor}})v / l_{\text{cor}} \approx 10^{-4} \text{ N m}^{-2}$, implying $\hat{\Gamma}_z^V \approx 5 \times 10^{15} \text{ Nm}$.

This may overestimate $\hat{\Gamma}_z^V$. A stable layer may exist at the top of the FOC; see, e.g., Loper (2007), Buffett (2010). Braginsky (1999) pointed out that the light material released during the freezing of the SIC may preferentially congregate near the ICB, and that this may answer unresolved questions about the geomagnetic secular variation (Braginsky 1984). Turbulent motions in a buoyantly stable layer tend to be damped preferentially in the direction of stratification, and this reduces the macroscale momentum transport across the layer (e.g., Gargett 1984; Davidson 2004). Waves in such a layer may increase what ν alone can do in transporting macroscale momentum (e.g., Rogers and Glatzmaier 2006). But it is doubtful if they can transport it as effectively as ν_T for fully convective turbulence far from boundaries.

Though these and similar arguments lack rigor, the above estimates of $\hat{\Gamma}^V$ are less than the target torque, but not vastly so (cf. Kuang and Bloxham 1997; Brito et al. 2004; Deleplace and Cardin 2006; Buffett and Christensen 2007).

The Topographic Torque

The likelihood that there are inverted mountains and valleys on the CMB, and that these might create topographic torques large enough to explain the observed changes in LOD, was first suggested by Hide (1969). These irregularities are often

collectively called “bumps,” and their study was jokingly christened “geophrenology” by the late Keith Runcorn. Hide’s idea generated much interest and literature, e.g., Anufriev and Braginsky (1975, 1977a, b), Jault and Le Mouél (1989), Kuang and Bloxham (1993, 1997), Buffett (1998) and Kuang and Chao (2001). Seismic studies infer the bump height, $\mathcal{H}$, is of order 1 km (e.g., Tanaka 2010). See *Earth’s Structure, Lower Mantle*.

Topographic coupling between the FOC and its boundaries depends on deviations from sphericity in the shapes of the CMB and ICB. The fluid pressure, p , creates surface fractions, $\hat{\mathbf{T}}^T = p\mathbf{n}$ and $\tilde{\mathbf{T}}^T = -p\mathbf{n}$, that are not purely radial. The resulting topographic torques on the CMB and ICB are

$$\begin{aligned}\hat{\mathbf{T}}^T &= \oint_{\hat{S}} p \mathbf{r} \times \mathbf{n} \, dA, \\ \tilde{\mathbf{T}}^T &= -\oint_{\tilde{S}} p \mathbf{r} \times \mathbf{n} \, dA.\end{aligned}\quad (3a, b)$$

Equal but opposite torques act on the FOC, so that (cf. Eq. 1g)

$$\mathbf{T}^T = -\hat{\mathbf{T}}^T - \tilde{\mathbf{T}}^T = -\int_V \mathbf{r} \times \nabla p \, dV. \quad (3c)$$

We define the CMB and ICB by

$$r = r_o + \hat{h}(\theta, \phi), \quad r = r_i + \tilde{h}(\theta, \phi), \quad (4a, b)$$

where (r, θ, ϕ) are spherical coordinates. Eq. 3a, b can be simplified if it is assumed that $|\hat{h}|/r_o \ll 1$, $|\tilde{h}|/r_i \ll 1$, $|\nabla \hat{h}| \ll 1$ and $|\nabla \tilde{h}| \ll 1$; see RA12. The projection of Eq. 3a, b onto the spheres $\hat{S}$ and $\tilde{S}$ are then

$$\begin{aligned}\hat{\mathbf{T}}^T &= \oint_{\hat{S}} \hat{h} \mathbf{r} \times \nabla p \, dA., \\ \tilde{\mathbf{T}}^T &= -\oint_{\tilde{S}} \tilde{h} \mathbf{r} \times \nabla p \, dA.. \end{aligned}\quad (4c, d)$$

The torques $\hat{\mathbf{T}}^T$ and $\tilde{\mathbf{T}}^T$ obviously depend on variations in p in the FOC, and we consider next the causes and magnitudes of these. This necessitates a considerable digression. The first step is to develop a reference state.

Convection mixes the FOC so well that, except in thin boundary layers at the CMB and ICB, it is chemically and thermodynamically homogeneous. It is therefore isentropic, i.e., its specific entropy, S , is uniform. The core is an unknown mixture of all elements, but the basics can be understood by assuming that it is a binary alloy of Fe and a lighter element, X , whose mass fraction is X . It is usually supposed

that X is mostly Si or S, but it is unnecessary to be specific here. Except in boundary layers,

$$\begin{aligned}S &= S_a = \text{Constant}, \\ X &= X_a = \text{Constant, in the FOC},\end{aligned}\quad (5a, b)$$

where the suffix a stands for “adiabatic”.

Although fast enough to mix the core thoroughly, core flows are slow compared with the speed of sound, u_s ($\approx 10^4 \text{ m s}^{-1}$). The primary dynamical balance is therefore hydrostatic and, allowing for centrifugal forces, it is governed by

$$\begin{aligned}\nabla p_a &= \rho_a (\mathbf{g}_a - \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{r})) \\ &= \rho_a \left(\mathbf{g}_a + \frac{1}{2} \nabla (\boldsymbol{\Omega} \times \mathbf{r})^2 \right),\end{aligned}\quad (5c)$$

where $\boldsymbol{\Omega} = \Omega \mathbf{1}_z$ is the angular velocity of the Earth and $\mathbf{g}$ is the gravitational acceleration. Newtonian gravitation theory requires that

$$\nabla \times \mathbf{g} = \mathbf{0}, \quad \nabla \cdot \mathbf{g} = -4\pi G \rho, \quad (5d, e)$$

where G is the constant of gravitation. It follows that

$$\nabla p_a = \rho_a \mathbf{g}_e = -\rho_a \nabla \Phi_e, \quad \text{where } \mathbf{g}_e = -\nabla \Phi_e \quad (5f, g)$$

is the effective gravitational field and $\Phi_e = \Phi_a - \frac{1}{2}(\boldsymbol{\Omega} \times \mathbf{r})^2$ is the “effective gravitational potential.” Eq. 5d shows that p_a , ρ_a , ... are constant on equipotential surfaces:

$$\begin{aligned}p_a &= p(\Phi_e, S_a, X_a), \\ \rho_a &= \rho(\Phi_e, S_a, X_a) = -\partial p(\Phi_e, S_a, X_a) / \partial \Phi_e, \dots\end{aligned}\quad (5h, i)$$

The effect of the centrifugal forces is quantified by $\varepsilon_\Omega = \Omega^2 r/g$. This is small, varying from 1.7×10^{-3} at the CMB to 1.5×10^{-3} at the ICB. The deviation of the equipotential surfaces from spheres is therefore small, as are deviations caused by the gravitational field produced by density anomalies in the mantle and SIC, quantified below. It is therefore helpful to refer to departures from a “reference state” that is spherically symmetric: $\Phi = \Phi^s(r)$, $p = p^s(r)$, $\rho = \rho^s(r)$, $T = T^s(r)$, etc., where T is temperature. There are large departures from adiabaticity in boundary layers and smaller departures throughout the FOC that are of two main types:

- (a) *Deviations from Φ^s due to rotation and density anomalies in the mantle and SIC.* These will be denoted by a prime, e.g., $p'_a = p_a - p^s$. Rotation produces the larger deviation but, as will be seen below, this is less relevant to LOD variations than the anomaly created by the mantle, which in the FOC is dominantly

$$\Phi'_a = A'(r/r_o)^2 \sin^2 \theta \cos 2\phi, \quad (A' > 0) \quad (6)$$

Wahr and de Vries (1989), Forte et al. (1994). The value of the constant A' is about $1,300 \text{ m}^2 \text{ s}^{-2}$, according to Defraigne et al. (1996) and about $2,300 \text{ m}^2 \text{ s}^{-2}$ according to Forte et al. (1994); our compromise will be $A' = 1,800 \text{ m}^2 \text{ s}^{-2}$. By Eq. 5i, $p'_a \approx -\rho_a^s \Phi'_a$. Therefore $\varepsilon_a = p'_a/p_a^s$ is 10^{-4} on the CMB equator and 10^{-5} at the ICB equator.

(b) *Deviations created by convection.* We use the notation

$$\rho = \rho_a + \rho_c, \quad (7a)$$

and similarly for other variables. The Earth radiates energy into space at a rate estimated to exceed 43 TW (e.g., §4.1.5 of Schubert et al. 2001). We take an extreme position by supposing the entire 43 TW emerges from the core. The outward heat flux in the FOC is the sum of the convective heat flux q_c and the adiabatic heat flux $q_a = -KdT^s/dr$, where K is thermal conductivity. Though the latter may be as much as 5 TW, we ignore it. Then $q_c = 0.28 \text{ W m}^{-2}$ at the CMB. We take

$$q_c = \rho c_p \overline{T_c V_r}, \quad (7b)$$

where c_p ($\approx 800 \text{ J kg}^{-1} \text{ K}^{-1}$) is the specific heat at constant pressure, p . The overline denotes a horizontal average over the flow, which is undoubtedly highly turbulent. For $V_r = 10^{-4} \text{ m s}^{-1}$, it follows that $T_c = 3.5 \times 10^{-4} \text{ K}$. As $\hat{T}_a \approx 4,000 \text{ K}$ (e.g., Kawai and Tsuchiya 2009), $\varepsilon_c = T_c/T_a$ is less than 10^{-7} , which is 3–4 orders of magnitude smaller than ε_a . Even this is an overestimate; it has never been suggested that Q_c is larger than 15 TW. The smallness of ε_Ω , ε_a , and ε_c means that all these effects can be treated as perturbations of the reference state.

As $p'_a(r, \theta, \phi) \gg p_c(r, \theta, \phi)$, it is sensible to consider first the effect of p'_a by introducing the “adiabatic topographic torques” on the mantle, ICB, and FOC:

$$\begin{aligned} \hat{\Gamma}_a^T &= \oint_S p_a \mathbf{r} \times \mathbf{n} \, dA, \\ \tilde{\Gamma}_a^T &= -\oint_S p_a \mathbf{r} \times \mathbf{n} \, dA, \\ \Gamma_a^T &= -\int_V \mathbf{r} \times \nabla p_a \, dV. \end{aligned} \quad (8a, b, c)$$

If the CMB (ICB) were an equipotential or if it were spherical, $\hat{\Gamma}_a^T$ ($\tilde{\Gamma}_a^T$) would vanish according to Eq. 8a, b, but generally these torques are nonzero. They can be evaluated only if $\hat{p}(\tilde{p})$ is known on the CMB (ICB). It will be

shown in the next section that $\hat{\Gamma}_a^T$ and $\tilde{\Gamma}_a^T$ are intimately related to what we shall call “adiabatic gravitational torques.” We therefore postpone further discussion and estimation of adiabatic topographic torques.

Consider the torque $\hat{\Gamma}_c^T$ associated with the convective motions in the FOC:

$$\begin{aligned} \hat{\Gamma}_c^T &= \oint_S \hat{h} \mathbf{r} \times \nabla p_c \, dA, \\ \hat{\Gamma}_{c,z}^T &= \oint_S \hat{h} \partial_\phi p_c \, dA. \end{aligned} \quad (9a, b)$$

Reasons will be given in the section on “The Magnetic Torque” why core flow may be well described by the magnetostrophic approximation Eq. 20a, and why, deep in the core, Coriolis and Lorentz forces are comparable, implying a magnetic field strength $\mathcal{B}$ there of about 2 mT, or about four times greater than the typical field strength $\mathcal{B}_o$ on the CMB. The Lorentz force is therefore 16 times less on the CMB than in the bulk of the core. Also, as g_ϕ is small, $\partial_\phi p_c \approx -2\Omega\rho_0 r_o V_\theta \cos \theta \sin \theta$ should be a good approximation to the ϕ -component of Eq. 20a on the CMB. Therefore (Hide et al. 1993)

$$\hat{\Gamma}_{c,z}^T = -2\Omega\rho_0 r_o \oint_S \hat{h}(\theta, \phi) V_\theta(r_o, \theta, \phi) \cos \theta \sin \theta \, dA. \quad (9c)$$

In principle, $\hat{\Gamma}_{c,z}^T$ can be estimated by extracting $\hat{h}$ from seismological analysis, and by using the $V_\theta(r_o, \theta, \phi)$ inferred from the core surface motion. In practice, this is difficult and has generated controversy. Eq. 9c suggests that

$$\hat{\Gamma}_{c,z}^T = O(2\Omega\rho\mathcal{V}\mathcal{H}r_o^3), \quad (9d)$$

which is 10^{18} Nm for a bump height of $\mathcal{H} = 100 \text{ m}$. Such a bump height is well within the bounds set by recent seismic investigations (e.g., Tanaka 2010). Equation 9b indicates, however, that Eq. 9d may be a serious overestimate because p_c is a single-valued function and $\partial_\phi p_c$ is as often positive as negative in the integrand of Eq. 9b. Though $\pm 2\Omega\rho\mathcal{V}r_o$ is a reasonable estimate of $\partial_\phi p_c$ at most points on the CMB, considerable cancellation is likely when evaluating the integral in Eq. 9b. There is even an outside chance that the cancellation might be complete; see Anufriev and Braginsky (1978b).

Reliable estimation of the convective topographic torque must probably await careful experiments and allied theory. No argument has so far convincingly demonstrated that topography can create torques of the target magnitude of 10^{18} Nm but, equally, none have shown that it cannot.

The Gravitational Torque

The gravitational torque on a body V of density $\rho(\mathbf{x})$ in a gravitational field $\mathbf{g}(\mathbf{x})$ is

$$\mathbf{\Gamma}^G = \int_V \rho \mathbf{r} \times \mathbf{g} dV. \quad (10a)$$

This volume integral can be usefully transformed into a surface integral by drawing on the analogy between the theories governing Newtonian gravitation and electrostatics, the only difference between these theories being one of sign: like charges repel but all bodies attract gravitationally. It can be shown that

$$\begin{aligned} \rho g_i &= \nabla_j S_{ij}^G, \quad \text{where} \quad S_{ij}^G \\ &= -\frac{1}{4\pi G} \left(g_i g_j - \frac{1}{2} g^2 \delta_{ij} \right) \end{aligned} \quad (10b, c)$$

is the gravitational stress tensor, the gravitational pressure $-g^2/8\pi G$ being also the gravitational energy density. Equations 10b, c enable 10a to be written as a surface integral:

$$\mathbf{\Gamma}^G = -\frac{1}{4\pi G} \oint_S \mathbf{r} \times \left[(\mathbf{n} \cdot \mathbf{g}) \mathbf{g} - \frac{1}{2} g^2 \mathbf{n} \right] dA, \quad (10d)$$

where $\mathbf{n}$ points out of V . See RA12 and Appendix B of Braginsky and Roberts (1995) for derivations of these results. When they are applied below, $\mathbf{n}$ on the CMB and SIC will, as previously defined, be oriented approximately parallel to $\mathbf{r}$.

By Eq. 10a, the gravitational torque on the FOC due to the mantle and SIC is

$$\mathbf{\Gamma}^G = \int_V (\rho_a + \rho_c) \mathbf{r} \times (\mathbf{g}_a + \mathbf{g}_c) dV = \mathbf{\Gamma}_a^G + \mathbf{\Gamma}_c^G, \quad (11a)$$

where $\mathbf{\Gamma}_a^G$ and $\mathbf{\Gamma}_c^G$ are the adiabatic and convective parts of $\mathbf{\Gamma}^G$:

$$\begin{aligned} \mathbf{\Gamma}_a^G &= \int_V \rho_a \mathbf{r} \times \mathbf{g}_a dV, \\ \mathbf{\Gamma}_c^G &= \int_V \mathbf{r} \times (\rho_c \mathbf{g}_a + \rho_a \mathbf{g}_c + \rho_c \mathbf{g}_c) dV. \end{aligned} \quad (11b, c)$$

It was pointed out earlier that $\rho_c = O(10^{-4} \rho'_a)$, $g_c = O(10^{-4} g'_a)$, etc. Apparently therefore $\mathbf{\Gamma}_c^G = O(10^{-4} \mathbf{\Gamma}_a^G)$, making it sensible to focus first on the adiabatic torque.

Consistent with hydrostatic balance in the FOC (see Eq. 5f), Eqs. 8c and 11b, give

$$\mathbf{\Gamma}_a^{G+T} = \mathbf{\Gamma}_a^G + \mathbf{\Gamma}_a^T = \int_V \mathbf{r} \times (\rho_a g_a - \nabla p_a) dV = \mathbf{0}. \quad (12a)$$

By Eqs. 8a, b and 10d and the continuity of $\mathbf{g}$ and p , we also have

$$\begin{aligned} \hat{\mathbf{\Gamma}}_a^{G+T} &= \oint_S \mathbf{r} \\ &\times \left\{ p_a \mathbf{n} + (4\pi G)^{-1} \left[(\mathbf{n} \cdot \mathbf{g}_a) g_a - \frac{1}{2} g_a^2 \mathbf{n} \right] \right\} dA, \end{aligned} \quad (12b)$$

$$\begin{aligned} \tilde{\mathbf{\Gamma}}_a^{G+T} &= -\oint_S \mathbf{r} \\ &\times \left\{ p_a \mathbf{n} + (4\pi G)^{-1} \left[(\mathbf{n} \cdot \mathbf{g}_a) g_a - \frac{1}{2} g_a^2 \mathbf{n} \right] \right\} dA, \end{aligned} \quad (12c)$$

from which, in agreement with Eq. 12a,

$$\hat{\mathbf{\Gamma}}_a^{G+T} + \tilde{\mathbf{\Gamma}}_a^{G+T} = \mathbf{0}. \quad (12d)$$

If the torques $\hat{\mathbf{\Gamma}}_a^{G+T}$ and $\tilde{\mathbf{\Gamma}}_a^{G+T}$ are nonzero, $\hat{\mathbf{\Omega}}$ and $\tilde{\mathbf{\Omega}}$ evolve. The consequent change in the relative orientation of the mantle and SIC modifies $\mathbf{g}_a$ and p_a in Eq. 12b, c so that the system evolves toward a configuration of minimum energy E . In this configuration

$$\hat{\mathbf{\Gamma}}_a^{G+T} = \mathbf{0}, \quad \tilde{\mathbf{\Gamma}}_a^{G+T} = \mathbf{0}. \quad (13a, b)$$

If this minimum energy, torque-free state is perturbed, the restoring GT-torques (as we shall call them) set up a “gravitational oscillation” of the SIC relative to the mantle.

To give a simple example, suppose that the gravitational anomaly defined by Eq. 6 is created by sources entirely within the mantle, the CMB having no bumps, so that $\hat{\mathbf{\Gamma}}_{a,z}^{G+T} = \hat{\mathbf{\Gamma}}_{a,z}^G$. Similarly, suppose the SIC is spherical but has internal sources that above the ICB produce the gravitational anomaly

$$\Phi_a'' = A''(r_i/r)^3 \sin^2 \theta \cos 2(\phi - \varphi), \quad (A'' > 0), \quad (14a)$$

where φ is the angular displacement of the system from the stable state, $\varphi = 0$, in which Eq. 13a, b hold. Eq. 12b, c show that

$$\begin{aligned} \hat{\mathbf{\Gamma}}_{a,z}^G &= -\tilde{\mathbf{\Gamma}}_{a,z}^G = \Gamma_0^G \sin 2\varphi, \quad \text{where} \\ \Gamma_0^G &= 8A'A''r_i^3/3Gr_o^2 (> 0). \end{aligned} \quad (14b, c)$$

These torques vanish for the stable minimum energy states $\varphi = 0, \pi$ (and also for the unstable $\varphi = \pm \frac{1}{2}\pi$). Small departures from a stable state satisfy

$$\hat{C}d_t^2\tilde{\varphi} = 2\Gamma_0^G(\tilde{\varphi} - \hat{\varphi}), \quad \tilde{C}d_t^2\tilde{\varphi} = 2\Gamma_0^G(\tilde{\varphi} - \hat{\varphi}), \quad (14d, e)$$

where $\hat{C}$ ($= 7.12 \times 10^{37} \text{ kg m}^2$) and $\tilde{C}$ ($= 5.86 \times 10^{34} \text{ kg m}^2$) are the polar moments of inertia of mantle and SIC, respectively. The frequency, ω^G , of the oscillation is

$$\omega^G = \left[2(\hat{C} + \tilde{C})\Gamma_0^G/\tilde{C}\tilde{C} \right]^{1/2} \approx \left[2\Gamma_0^G/\tilde{C} \right]^{1/2}. \quad (14f)$$

Although an anomaly of the form of Eq. 14a could be produced by density variations within the SIC, it is more plausibly created by SIC topography for the following reasons. It is generally believed that the SIC is the result of freezing of the FOC, an ongoing process even today (Jacobs 1953). An alloy generally changes its composition when it changes phase. The rather large density jump at the ICB, $\tilde{\Delta} = \tilde{\rho}(r_i) - \rho(r_i) \approx 600 \text{ kg m}^{-3}$, is hard to attribute to contraction on freezing but can be readily explained as a small reduction in X on freezing. Phase equilibrium at the ICB implies $T_a^s(\Phi_a, S_a, X_a) = T_m(p_a, X_a)$, where T_m is the melting temperature. This implies that the ICB is an equipotential surface. Since $\Phi = \Phi_a^s(r) + \Phi_a'(r, \theta, \phi)$ where $|\Phi_a'/\Phi_a^s| \ll 1$, Taylor expansion, using Eq. 4b, shows that $\Phi_a^s(r_i) + \tilde{g}\tilde{h}(\theta, \phi) + \Phi_a'(r_i, \theta, \phi)$ is approximately constant, where $\tilde{g} = -g_{a,r}^s(r_i) = \partial_r \Phi_a^s(r_i) (> 0)$ is gravity at the ICB. It follows that

$$\begin{aligned} \tilde{h} &= -\Phi_a'(r_i, \theta, \phi)/\tilde{g} = \tilde{\varepsilon} \sin^2 \theta \cos 2\phi, \\ \tilde{\varepsilon} &= -A'(r_i/r_0)^2/\tilde{g}. \end{aligned} \quad (14g, h)$$

This shows how the gravitational anomaly in the mantle imposes its $n = m = 2$ preference on the SIC. It makes the otherwise ad hoc assumption of Eq. 14a seem perfectly reasonable. The condition that $\tilde{h}$ creates Eq. 14a, for $\varphi = 0$ and $r - r_i \gg \tilde{h}$ is

$$A''/A' = 4\pi G r_i^3 \tilde{\Delta}/5r_0^2 \tilde{g} \approx 0.0034. \quad (14i)$$

The maximum bump height on the ICB is $|\tilde{\varepsilon}| \approx 50 \text{ m}$. Nonzero φ corresponds to a rotated SIC. Such a rotation is to be expected; core turbulence continually subjects the SIC to (topographic) torques that continuously change its orientation. Two relaxation processes act to restore the ICB to its equipotential: (i) flow within the SIC, (ii) new freezing/melting on the ICB. If either were instantaneous, there would be no torque between the mantle and SIC, but both appear to act on much longer time scales than core turbulence, so that SIC topography is almost “frozen” to the SIC as it turns.

Concerning (i), the viscosity of the SIC is plausibly much less than the viscosity of the mantle. According to Schubert et al. (2001) $\hat{\nu} \approx 5 \times 10^{19} \text{ m}^2 \text{ s}^{-1}$ in the deep mantle but, according to Mound and Buffett (2006), $\hat{\nu} \gtrsim 10^{13} \text{ m}^2 \text{ s}^{-1}$. Whereas mantle anomalies are essentially “frozen in,” slow motions within the SIC created by stresses exerted by the

FOC on the ICB can gradually restore equilibrium (Yoshida et al. 1996; Buffett 1997). Concerning (ii), the thermodynamic disequilibrium created by the misalignment of the ICB from its equipotential surface is slowly removed by new freezing of the FOC or new melting of the SIC. This processes has not been fully explored (but see Fearn et al. 1981; Morse 1986). The possible significance of melting/freezing processes on SIC structure has been recently investigated by Alboussière et al. (2010) and Monnereau et al. (2010).

Interest in gravitational torques and oscillations was sparked by Buffett (1996). We follow him but by a different method, making use of Eq. 14c, i:

$$\Gamma_0^G = 32\pi r_i^6 \tilde{\Delta} A'^2 / 15r_0^4 \tilde{g} \approx 6.7 \times 10^{19} \text{ Nm} \quad (15a)$$

By Eq. 14f, the frequency of the oscillation is $\omega^G \approx 4.8 \times 10^{-8} \text{ s}^{-1}$, with a period of

$$\tau^G = 2\pi/\omega^G \approx 4.1 \text{ years}. \quad (15b)$$

According to Buffett et al. (2009), gravitational oscillations are mainly responsible for the LOD variations shown in Fig. 1. Mound and Buffett (2006) obtain $\Gamma_0^G \approx 1.5 \times 10^{20} \text{ Nm}$.

Equations 14d, e imply, for some t_0 ,

$$\begin{aligned} \hat{\Omega} &= \hat{\Omega}_0 + d_t \hat{\phi} \\ &= \hat{\Omega}_0 + \left(2\Gamma_0^G/\tilde{C}\omega^G \right) \left(\tilde{\phi} - \hat{\phi} \right)_{\max} \sin \omega^G(t - t_0). \end{aligned} \quad (15c)$$

The amplitude of the gravitational oscillation is therefore related to that of the variation, ΔP , in LOD by

$$\left(\tilde{\phi} - \hat{\phi} \right)_{\max} = \pi \hat{C} \omega^G \Delta P / \Gamma_0^G P_0^2 \approx 1.2, \quad (15d)$$

for $\Delta P = 1 \text{ ms}$. This gives a maximum angular velocity difference of $\omega^G \left(\tilde{\phi} - \hat{\phi} \right)_{\max} \approx 2 \text{ year}^{-1}$. Furthermore the peak-to-peak variation in the radial gravitational acceleration at the Earth's surface, $r = r_E$, is

$$\Delta g_r''(r_E) = \frac{12A''}{r_i} \left(\frac{r_i}{r_E} \right)^4 \left(\hat{\phi} - \tilde{\phi} \right)_{\max}^2 \simeq 4 \text{ nGal}. \quad (15e)$$

This value is too small by roughly a factor of 5 to be detectable by the GRACE satellite system (e.g., Wahr et al. 2006).

One limitation of this analysis is the neglect of electromagnetic stresses at the boundaries when they are in motion relative to the core fluid. It has been implicitly assumed that the SIC is completely decoupled from the fluid within the tangent cylinder (TC), the imaginary cylinder that touches the

ICB at its equator. This is particularly significant because the fluid dynamics inside and outside the TC are quite dissimilar. See Hide and James (1983), Heimpel and Aurnou (2007), and the next section. Because the SIC is as good an electrical conductor as the FOC (or better), it may be tightly coupled magnetically to C^N and C^S , as suggested by Braginsky (1970); see the next section. To examine the effect of this coupling, we make the extreme assumption that all the fluid in the TC is completely locked to the SIC. Because the mantle is a poor electrical conductor, this fluid is not well coupled to the mantle, so that the entire fluid column within the TC can co-rotate about O_z almost freely with the SIC. This suggests that, instead of Eq. 1g, h, a more useful division of the total angular momentum of the Earth might be based on

$$\begin{aligned}\hat{\Gamma} + \Gamma^{\text{TC}} + \Gamma^{\text{XTC}} &= 0, \\ \hat{\mathbf{M}} + \mathbf{M}^{\text{TC}} + \mathbf{M}^{\text{XTC}} &= \text{constant},\end{aligned}\quad (16a, b)$$

where $^{\text{TC}}$ refers to the TC and SIC locked together, and $^{\text{XTC}}$ refers to the part of the FOC exterior to the TC. The moment of inertia of the fluid within the TC is $2.12 \times 10^{35} \text{ kg m}^2$ which, when added to $\tilde{C}$, gives $C^{\text{TC}} = 2.71 \times 10^{35} \text{ kg m}^2$. Using this instead of $\tilde{C}$ in Eq. 14f, τ^G is lengthened from 4.1 years to

$$\begin{aligned}\tau_{\text{TC}}^G &= 2\pi/\omega_{\text{TC}}^G \approx 8.9 \text{ years}, \\ \text{where } \omega_{\text{TC}}^G &= \left[2(\hat{C} + C^{\text{TC}})\Gamma_0^G/\hat{C}C^{\text{TC}}\right]^{1/2}.\end{aligned}\quad (16c, d)$$

See also Mound and Buffett (2006).

Even though ρ_c/ρ_a , p_c/p_a , etc., are of order 10^{-4} , this does not mean that $\Gamma_a^{G+T}/\Gamma_c^{G+T}$ is as small as that. In fact, Eq. 13a shows that $\Gamma_a^{G+T} = 0$ in the minimum energy state. The adiabatic GT-torques dominate the convective torques only if φ is sufficiently large. Stated another way, a convective torque can be nullified by a small departure from the minimum energy state. Earlier, the torque on the SIC created by core turbulence was held responsible for causing φ to deviate from zero. This torque is essentially (magneto-)convective, and is nullified by the GT-torque for a tiny change in φ . Another way of estimating how tiny this φ is equates the magnitudes of the GT-torque, taken as $1.3 \times 10^{20} \varphi \text{ Nm}$ (see Eqs. 14b, c and 15d), and the convective torque, taken to have its target value of 10^{18} Nm . This gives $\varphi \approx 0.5^\circ$. Within this angle, the mantle and SIC are gravitationally locked together, over short time scales compared with those of the relaxation processes in the SIC described above. See Buffett and Glatzmaier (2000).

The Magnetic Torque

This section assumes that readers are familiar with pre-Maxwell EM theory and the fundamentals of MHD, including

the frozen flux theorem and Alfvén waves. Davidson (2001) contains the necessary background.

It may be useful to remind readers that the magnetic torque about O on a body V carrying a current of density $\mathbf{J}$ is the integrated moment of the Lorentz force, $\mathbf{J} \times \mathbf{B}$:

$$\Gamma^M = \int_V \mathbf{r} \times (\mathbf{J} \times \mathbf{B}) dV = \int_V r[B_r \mathbf{J} - J_r \mathbf{B}] dV. \quad (17a)$$

The Lorentz force can be expressed as a divergence:

$$\begin{aligned}(\mathbf{J} \times \mathbf{B})_i &= \nabla_j S_{ij}^M, \\ \text{where } S_{ij}^M &= \mu_0^{-1} \left(B_i B_j - \frac{1}{2} B^2 \delta_{ij} \right)\end{aligned}\quad (17b, c)$$

is the magnetic stress tensor. An alternative form of Eq. 17a is therefore

$$\Gamma^M = \mu_0^{-1} \oint_S \mathbf{r} \times \left[(\mathbf{n} \cdot \mathbf{B}) \mathbf{B} - \frac{1}{2} B^2 \mathbf{n} \right] dA, \quad (17d)$$

where the unit normal $\mathbf{n}$ to S points out of V . Therefore

$$\begin{aligned}\hat{\Gamma}_z^M &= -\mu_0^{-1} \oint_S \hat{\phi}_r \hat{B}_r \hat{B}_\phi dA, \\ \tilde{\Gamma}_z^M &= \mu_0^{-1} \oint_S \tilde{s} \tilde{B}_r \tilde{B}_\phi dA.\end{aligned}\quad (17e, f)$$

These results can be used as they stand to assess the magnetic coupling between the inferred core surface flow and the mantle. See Stix and Roberts (1984), Love and Bloxham (1994), Holme (1998). Here, however, we are more interested in forging a link between the observed changes in LOD and torsional waves. To explain what the latter are, it is necessary to consider some dynamical issues.

Most studies of core MHD are based on the Boussinesq approximation; see, e.g., Braginsky and Roberts (2007). This assumes constant density, $\rho_0 (\approx 10^4 \text{ kg m}^{-3})$, and expresses conservation of mass and momentum as

$$\begin{aligned}\nabla \cdot \mathbf{V} &= 0, & \partial_t \mathbf{V} + \mathbf{V} \cdot \nabla \mathbf{V} + 2\boldsymbol{\Omega} \times \mathbf{V} \\ &= -\nabla(p_c/\rho_0) + C\mathbf{g}_e + \mathbf{J} \times \mathbf{B}/\rho_0 + \nu_T \nabla^2 \mathbf{V}.\end{aligned}\quad (18a, b)$$

The accelerations in Eq. 18b are from inertia ($\partial_t \mathbf{V}$ and $\mathbf{V} \cdot \nabla \mathbf{V}$), rotation ($2\boldsymbol{\Omega} \times \mathbf{V}$), pressure (p_c), buoyancy ($C\mathbf{g}_e$), magnetic field ($\mathbf{J} \times \mathbf{B}/\rho_0$), and viscosity ($\nu_T \nabla^2 \mathbf{V}$). Thermal and compositional buoyancy, combined in the codensity C (Braginsky and Roberts 1995), maintains the flow and the magnetic field; see *Core Dynamo*.

The Coriolis force is generally more significant than the inertial and viscous forces. This is indicated by the smallness of the Ekman and Rossby numbers:

$$Ro = \mathcal{V}/\Omega\mathcal{L}. \quad (19)$$

See Eq. 2c for the definition of E . From $\mathcal{V} = 10^{-4} \text{ m s}^{-1}$, $\mathcal{L} = r_o$ and $v_T = 10^{-2} \text{ m}^2 \text{ s}^{-1}$ follow $Ro \approx 10^{-6}$ and $E \approx 10^{-11}$. This suggests that the inertial and viscous terms can be safely omitted from Eq. 18b, except on small length scales.

If the inertial and viscous forces are ejected from Eq. 18b, it becomes

$$2\rho_0\mathbf{\Omega} \times \mathbf{V}^N = -\nabla p_c + \rho_0 C\mathbf{g}_e + \mathbf{J} \times \mathbf{B}, \quad (20a)$$

where N stands for “non-geostrophic,” and “geostrophic” is defined below. Equations 18a and 20a define the “magnetostrophic approximation,” often used to describe the quasi-steady macroscales of core MHD. As the viscous term has been ejected, the only boundary condition that $\mathbf{V}^N$ must obey is

$$\mathbf{n} \cdot \mathbf{V}^N = 0, \quad \text{on the CMB and ICB.} \quad (20b)$$

The full boundary conditions of continuous $\mathbf{B}$ and $\mathbf{n} \times \mathbf{E}$ still apply. Because $\partial_t \mathbf{V}$ has been ejected from Eq. 20a, there are no Alfvén waves. Instead, the system evolves on the much longer ageostrophic time scale,

$$\begin{aligned} \tau^N &= 2\Omega\mathcal{L}^2/V_A^2 = \tau_\eta/\Lambda, \\ \text{where } \tau_\eta &= \mathcal{L}^2/\eta \approx 10^5 \text{ years} \end{aligned} \quad (20c, d)$$

is the free decay time for magnetic fields of scale $\mathcal{L}$, and Λ is the “Elsasser number”:

$$\begin{aligned} \Lambda &= V_A^2/2\Omega\eta, \quad \text{where} \quad V_A \\ &= \mathcal{B}/\sqrt{(\mu_0\rho_0)} \end{aligned} \quad (20e, f)$$

is the Alfvén velocity. Elsasser (1946) suggested that $\mathcal{B}$ is determined by a balance of Lorentz and Coriolis forces. Taking $j \approx \sigma\mathcal{V}\mathcal{B}$ this implies $\Lambda = 1$, $\mathcal{B} \approx 2 \text{ mT}$, and $V_A \approx 2 \text{ cm s}^{-1}$. It also gives $\tau^N \approx \tau_\eta \approx 2 \times 10^5 \text{ years}$ for $\mathcal{L} = r_o$.

In cylindrical coordinates (s, ϕ, z) , the ϕ -component of Eq. 20a is

$$2\Omega\rho_0 V_s^N = -\partial_\phi p_c + (\mathbf{J} \times \mathbf{B})_\phi. \quad (21a)$$

Integrate this over the surface, $\mathcal{C}(s)$, of the circular cylinder of radius s ($> r_i$) coaxial with Oz. The left-hand-side vanishes by mass conservation, as can be verified by integrating Eq. 18a over the interior, $\mathcal{L}(s)$, of $\mathcal{C}(s)$ and applying Eq. 20b to $\hat{\mathcal{N}}(s)$ and $\hat{\mathcal{S}}(s)$, the spherical caps of $\mathcal{C}(s)$ on the CMB that complete the boundary of $\mathcal{I}(s)$. It follows that

$$\int_{\mathcal{C}(s)} (\mathbf{J} \times \mathbf{B})_\phi \, dA = 0 \quad (21b)$$

If $s < r_i$, there are two cylinders, $\mathcal{C}^N(s)$ and $\mathcal{C}^S(s)$, of radius s to the north and south of the SIC for which

$$\begin{aligned} \int_{\mathcal{C}^N(s)} (\mathbf{J} \times \mathbf{B})_\phi \, dA &= 0, & \int_{\mathcal{C}^S(s)} (\mathbf{J} \times \mathbf{B})_\phi \, dA \\ &= 0. \end{aligned} \quad (21c, d)$$

Equations 20b–d are examples of “Taylor’s constraint” (Taylor 1963). The cylinders $\mathcal{C}(s)$ are termed “Taylor cylinders.” Of these, $\mathcal{C}(r_i)$ is the tangent cylinder (TC).

It is obviously possible to assign a $\mathbf{J}$ which creates a $\mathbf{B}$ that contradicts Eqs. 21b–d, at least initially. This shows that Eq. 20a is an oversimplification. That approximation rested on discarding the inertial force in comparison with the Coriolis force. Consider however the class of “geostrophic flows”:

$$\mathbf{v} = v(s, t) \mathbf{1}_\phi. \quad (22a)$$

The corresponding Coriolis acceleration is

$$\begin{aligned} 2\rho_0\mathbf{\Omega} \times \mathbf{v} &= -\nabla\chi, \\ \text{where } \chi &= 2\Omega\rho_0 \int v(s, t) \, ds \end{aligned} \quad (22b, c)$$

can be absorbed into p_c . Coriolis forces are therefore totally ineffective when they act on geostrophic flows. Other forces previously abandoned in comparison with Coriolis forces become influential, especially the inertial forces, which must be restored when analyzing the geostrophic part of core flow. This recovers the Alfvén wave, or something very like it, called the “torsional wave.” They share a common time scale:

$$\tau_A = r_o/V_A \approx 6 \text{ years.} \quad (22d)$$

That this is also the time scale t_{LOD} of the semi-decadal variations of in Fig. 1a, b may not be a coincidence, as argued by Gillet et al. (2010).

The geostrophic part $\mathbf{v}$ of $\mathbf{V}$ can be extracted from $\mathbf{V}$ by taking the “geostrophic average,” $\langle V_\phi \rangle$, of V_ϕ : for $s > r_i$, this average is defined by

$$\begin{aligned} v &= \langle V_\phi \rangle \equiv \frac{1}{\hat{A}}(s) \int_{\mathcal{C}(s)} V_\phi \, dA, & \text{so that} \\ \mathbf{V}^N &= \mathbf{V} - v\mathbf{1}_\phi, \end{aligned} \quad (22e)$$

Core-Mantle Coupling,

Fig. 2 Schematics showing (a) geostrophic flows in the core, V^g , and (b) plan view of an initially cylindrical magnetic field (dashed line) distorted by v . The restoring Lorentz torques on the distorted magnetic field, B_s (solid line), lead to the cylindrical propagation of torsional waves. (Adapted from Dumberry 2007)

where $\hat{A}(s) = 4\pi s z_1$ is the area of $C(s)$, and $z_1(s) = \sqrt{(r_o^2 - s^2)}$ is the semi-length of its sides. The axial angular momentum of the FOC is carried by v . Therefore, insofar as the rotation of the SIC is locked to that of the fluid in the TC, the angular momentum, $M_z + \tilde{M}_z$, of the entire core can be derived from the zonal part of the inferred core surface flow. The LOD record provides $\tilde{M}_z$. Therefore Eq. 1h can be tested: $\hat{M}_z = -(M_z + \tilde{M}_z)$. Results have been gratifying; see Jault et al. (1988), Jackson (1997) and Fig. 1c above. The previous section indicates however that the mantle and SIC are not locked together but take part in a gravitational oscillation having a period (4–9 years) similar to the torsional wave period $\tau_A \approx 6$ years. The implied convolvment of gravitational and magnetic coupling complicates the task of extracting information about either; see Buffett et al. (2009).

In a torsional wave, the geostrophic cylinders are in relative angular motion about their common (polar) axis; see Fig. 2a. The response **b** of **B** to the motion **v** can, as for an Alfvén wave, be visualized using the frozen flux theorem, the field lines behaving like elastic strings threading the cylinders together and opposing their relative motion; see Fig. 2b. The resulting torque on a cylinder supplies the restoring force for a wave, the mass of the cylinders providing the inertia. Whenever **J** and **B** contradict Eqs. 21b–d, a torsional wave is launched that travels in the $\pm s$ -directions.

The canonical torsional wave equation is

$$\frac{\partial^2 \zeta}{\partial t^2} = \frac{1}{s^2 \hat{A}(s)} \frac{\partial}{\partial s} \left[s^2 \hat{A}(s) V_A^2(s) \frac{\partial \zeta}{\partial s} \right], \quad (23)$$

where $\zeta(s, t) = v/s$ is the angular velocity of $C(s)$ and $V_A(s) = \mathcal{B}_s(s)/(\mu_0 \rho_0)^{1/2}$ is the Alfvén velocity based on the mean $(B_s^N)^2$ over $C(s)$: $\mathcal{B}_s^2(s) = \langle (B_s^N)^2 \rangle$. Equation 23 is called canonical because it displays the essential nature of torsional waves clearly. It is however not only incomplete but also ignores magnetic coupling to the mantle and SIC. Equation 23 presupposes that the field, $\mathbf{B}^N$, on which the waves ride is axisymmetric. In this case, Eq. 23 has a severe

singularity at $s = 0$ which excludes physically acceptable solutions. This difficulty can be evaded by supposing that the TC rotates as a solid body, as suggested by Braginsky (1970), and by applying Eq. 23 only in XTC. For general, non-axisymmetric $\mathbf{B}^N$, the regular singularity at $s = 0$ is harmless, but unfortunately Eq. 23 is then incomplete. The terms missing from Eq. 23 represent the transmission of torque from one Taylor cylinder to another by the potential field outside the core. As the terms are troublesome if retained, they are usually abandoned, with an unsubstantiated claim that they are too small to be worth keeping. Whether they are retained or abandoned, the wave equation admits normal mode solutions, i.e., solutions in which ζ is proportional to $\exp(-i\omega t)$, where every ω is real, as shown in RA12. When magnetic coupling to the mantle is included, ω acquires a negative imaginary part, representing the ohmic losses in the mantle. The inclusion of magnetic coupling is highly relevant to our focus here, but it clearly adds another layer of complexity.

In view of these theoretical obstacles, the reader may wonder whether computer simulation would not provide a simpler approach. It is however difficult to extract evidence of torsional waves from geodynamo simulations. This is because it is not yet possible to attain geophysically realistic magnetic Prandtl numbers, Pm , in numerical integrations. The importance of viscous damping of torsional waves can be assessed by the ratio of the torsional wave time scale, $\tau_A = r_o/V_A$, to the spin-up time scale, $\tau_{SU} = \sqrt{(r_o^2/2\Omega\nu)}$, which is their viscous decay time; see Roberts and Soward (1972). This ratio,

$$\tau_A/\tau_{SU} = 2(\Omega\nu)^{1/2}/V_A = \sqrt{(Pm/\Lambda)}, \quad (24)$$

is small for the Earth ($\sim 10^{-3}$) but inconveniently large in simulations (≥ 0.1). See Wicht and Christensen (2010) for recent simulations of torsional waves.

Space limitations do not permit the mathematical theory of torsional waves to be presented here; see Braginsky (1970), Roberts and Soward (1972), Jault (2003), Dumberry (2007) and RA12. The principal aim in what follows is to outline the

underlying physics, that has been employed in theoretical studies, and that will have to be incorporated in numerical models in the future, when computer technology has advanced far enough to permit core MHD to be modeled more faithfully. Our discussion here sidesteps interesting and as yet incompletely answered questions, the first of which is whether torsional waves are involved in any essential way with the semi-decadal LOD periodicity; might not the gravitational oscillation described in the last section be mainly responsible? The answer is unclear but core field strengths of 2 mT suggest that torsional waves very effectively link together geostrophic motions throughout the core, and that torsional waves therefore necessarily accompany gravitational oscillations. This obviously does not imply that torsional waves couple well to the mantle; if the mantle were an electrical insulator, there would be no magnetic coupling of core and mantle at all. The waves would then be detectable only through the inferred core surface motion. Strong magnetic coupling of the waves to the mantle raises difficult questions about both the excitation and dissipation of the waves. As shown below, the waves are mainly and heavily damped by ohmic dissipation in the mantle. What maintains the waves against this energy loss? No definitive answer has been given to this very significant question. Core turbulence may be directly responsible, or indirectly through the Reynolds magneto-stresses it exerts on the SIC or on the TC. Buffett et al. (2009) find evidence for wave generation at the TC. Core turbulence would presumably excite many damped normal modes. This might help to explain some of the recently discovered short time scales of core surface motions (Olsen and Manda 2008; Finlay et al. 2010). It has not been established unequivocally that the 6 year period is the fundamental mode. Though often questioned, evidence of a 60 periodicity exists. This longer period signal might be representative of the fundamental mode but would require current estimates of $\mathcal{B}_s(s)$ to be revised downward.

These matters are beyond the scope of this review. We shall merely sketch, mostly in a qualitative way, the approximate theory that is currently the most complete. We also aim to expose its strengths and weaknesses.

Underlying the entire theory is the idea that core flow can be neatly separated into geostrophic motions of short time scale, τ_A , and non-geostrophic motions of long time scale τ^N obeying Eq. 20a. In other words, the theory focusses on the large length scales of core flow, in the belief that this includes the fundamental torsional wave mode of greatest interest. The torsional wave therefore rides on a flow satisfying Taylor's constraints Eqs. 21a–c. Because the Lehnert number, $\lambda = \tau_A / \tau^N = V_A / 2\Omega r_o = \omega_A / 2\Omega \approx 3 \times 10^{-5}$, is small, the time dependence of $\mathbf{B}^N$ can be ignored in torsional wave theory.

It was pointed out earlier that torsional waves are geostrophic motions in which the inertial force is crucial. The first

step in deriving the torsional wave equation is therefore to restore the time-dependent inertial force to Eq. 21a, obtaining

$$\rho_0 s \partial_t V_\phi + 2\Omega \rho_0 s V_s = -\partial_\phi p_c + s(\mathbf{J} \times \mathbf{B})_\phi, \quad (25a)$$

from which $\partial_t \zeta$ is extracted, by taking the geostrophic average; see Eq. 22e.

The evaluation of $(\mathbf{J} \times \mathbf{B})_\phi$ is simplified because E is small and the Lundquist number, $Lu = \tau_\eta / \tau_A = V_A r_o / \eta \approx 3 \times 10^4$, of the waves is large. In a first approximation, $E = Lu^{-1} = 0$. Then viscous and ohmic diffusion and the associated boundary conditions are discarded. In particular, the electric field created in the FOC by the waves simplifies to

$$\mathbf{e} = -\mathbf{v} \times \mathbf{B}^N - \mathbf{V}^N \times \mathbf{b} - \mathbf{v} \times \mathbf{b}, \quad (25b)$$

where $\mathbf{b}$ is the magnetic field of the waves. The term $-\mathbf{V}^N \times \mathbf{B}^N$ does not appear because it already acts on the Taylor state. The last term in Eq. 25b is also ignored because the wave amplitude is assumed to be small. The ratio of $-\mathbf{V}^N \times \mathbf{b}$ to $-\mathbf{v} \times \mathbf{B}^N$ is of order $A^N [b/v \sqrt{(\mu_0 \rho_0)}]^{-1}$, where $A = V/V_A$ is the Alfvén number, which for the non-geostrophic flow is about 0.1 (see above). As in an Alfvén wave, $v = O[b/\sqrt{(\mu_0 \rho_0)}]$, so that $|\mathbf{V}^N \times \mathbf{b}| \approx 0.1 |\mathbf{v} \times \mathbf{B}^N|$. This, combined with the fact that the inclusion of $-\mathbf{V}^N \times \mathbf{b}$ in $\mathbf{e}$ adds severe complications, encourages the neglect of $-\mathbf{V}^N \times \mathbf{b}$ in Eq. 25b, leaving

$$\mathbf{e} = -\mathbf{v} \times \mathbf{B}^N. \quad (25c)$$

The mantle and core are linked across a boundary layer of Ekman-Hartmann type; e.g., see Dormy et al. (2007). Because $Pm \ll 1$, this has a double structure. Viscosity acts only in an Ekman layer of thickness $d_v = \sqrt{(\nu/2\Omega)} \approx 0.1$ m; magnetic diffusion acts in a layer whose thickness is comparable with the EM skin depth, $d_\eta = (\frac{1}{2}|\omega|\mu_0\sigma)^{-1/2} \approx 10$ km. We therefore call this a “magnetic diffusion layer” (MDL), even though Coriolis and Lorentz forces affect its structure too. In the MDL, Eq. 25c is replaced by

$$\mathbf{e} = -\mathbf{v} \times \mathbf{B}^N - \eta \nabla \times \mathbf{b} \approx -\mathbf{v} \times \mathbf{B}^N - \eta \mathbf{1}_r \times \partial_r \mathbf{b}. \quad (26)$$

As $d_\eta/d_v \gg 1$, the Ekman layer is only a tiny part of the MDL. Ekman-Hartmann theory simplifies by discarding the Ekman part, setting $\nu = 0$ and abandoning the no-slip boundary conditions. The structure of the MDL still depends on rotation, and on the Elsasser number, Λ , defined in Eq. 20e.

The boundary layers play a vital role in linking ζ in the main bulk of the FOC to $\hat{\mathbf{b}}$ on the CMB and $\tilde{\mathbf{b}}$ on the ICB. They are therefore essential in determining $\hat{\mathbf{I}}^M$ and $\tilde{\mathbf{I}}^M$. At the CMB, $\mathcal{B} \approx 0.5$ mT and $\Lambda \approx 0.07$. The prevailing magnetic field, $\mathbf{B}^N$, therefore has very little effect on the boundary layer, which is controlled almost entirely by Coriolis forces and

magnetic diffusion. At the ICB, where $\mathcal{B}$ may be even an order of magnitude greater than at the CMB, $\Lambda > 1$, and Lorentz forces are too significant to ignore in the boundary layer. Further details are given in RA12.

The torque exerted by the waves on the mantle is proportional to the electrical conductivity, $\hat{\sigma}(v, \theta, \phi)$, of the mantle, which we assume is nonzero only in the layer $r_o < r < r_1 = r_o + d$ at the base of the mantle. The conductance of this layer is

$$\hat{\Sigma}(\theta, \phi) = \int_{r_o}^{r_1} \hat{\sigma}(r, \theta, \phi) dr. \quad (27a)$$

It is commonly assumed that $10^7 \text{ S} < \hat{\Sigma} < 10^9 \text{ S}$; we take $\hat{\Sigma} = 10^8 \text{ S}$ below.

Electric currents, $\hat{\mathbf{j}}$, flow in the mantle, $\hat{\mathbf{V}}$, either by leaking from the core or by electromagnetic induction, through the time dependence of the EM field on the CMB. We shall be interested in the penetration of the fields $\mathbf{b}$ and $\mathbf{e}$ of the waves, at frequencies ω of order $5 \times 10^{-8} \text{ s}^{-1}$. The resulting magnetic and electric fields, $\hat{\mathbf{b}}$ and $\hat{\mathbf{e}}$, in the mantle depend on ω and on L , the horizontal length scale imposed by $\mathbf{b}$ and $\mathbf{e}$ on the CMB. Associated with ω is the skin depth of the mantle:

$$\hat{d}_\eta = \left(\frac{1}{2} |\omega| \mu_0 \hat{\sigma}_o \right)^{-1/2}. \quad (27b)$$

Starting with Glatzmaier and Roberts (1995), theoreticians have usually simplified EM theory in the mantle by adopting the “thin-layer approximation” (TLA). This originated from the modeling of laboratory MHD experiments (see, e.g., Müller and Bühler 2001). It is easily applied and therefore popular, although the conditions for its validity are seldom mentioned or questioned. The TLA demands that $d \ll \hat{d}_\eta (\ll L)$. The horizontal part, $\hat{\mathbf{e}}_H$, of the electric field $\hat{\mathbf{e}}$ is then independent of r , so that

$$\hat{\mathbf{j}}_H = \hat{\sigma} \hat{\mathbf{e}}_H, \quad \text{and} \quad \hat{\mathcal{J}} = \hat{\Sigma} \hat{\mathbf{e}}_H, \quad (27c, d)$$

where $\hat{\mathcal{J}}$ is the total horizontal current carried by the layer.

It may be helpful to visualize the TLA as a mathematical limit, $d \rightarrow 0$, $\hat{\sigma} \rightarrow \infty$ with $\hat{\Sigma}$ held fixed. Then $\hat{\mathcal{J}}$ is a surface current responsible for a discontinuity in the magnetic field. If $\hat{\mathbf{b}} \left(= -\nabla \hat{\mathbf{w}} \right)$ is the potential field above the conducting layer,

$$\begin{aligned} \hat{\mathbf{b}}(r_o, \theta, \phi) - \hat{\mathbf{b}}(r_o, \theta, \phi) &= \mu_0 \hat{\mathcal{J}}(\theta, \phi) \times \mathbf{1}_r \\ &= \mu_0 \hat{\Sigma}(\theta, \phi) \hat{\mathbf{e}}_H(r_o, \theta, \phi) \times \mathbf{1}_r. \end{aligned} \quad (27e)$$

The potential field does not affect the torque, Γ^M , on the mantle, although it does contribute to the torque that each Taylor cylinder exerts on the others.

We contrast two proposed conductivity distributions. Buffett et al. (2002) inferred from their studies of nutational resonances that d is only 200 m and that $\hat{\sigma} = 3 \times 10^5 \text{ S m}^{-1}$, which is comparable to the core conductivity σ , and gives $\hat{d}_\eta = 10 \text{ km}$. The TLA should therefore be excellent in most applications. In contrast, the laboratory experiments of Ohta et al. (2008) suggest $\hat{\sigma} = 100 \text{ S m}^{-1}$ and $d = 3 \times 10^5 \text{ m}$; see also Yoshino (2010). This gives $\hat{d}_\eta = 2 \times 10^6 \text{ m}$, so it is doubtful if the TLA can be validly applied. The similar conductances of the models ($\hat{\Sigma} = 3/6 \times 10^7 \text{ S}$) are insufficient to justify the use of the TLA.

This completes our critique of the basics of torsional wave coupling to the mantle. Some of its consequences are unexpected; but most are not. Even dimensional reasoning leads to

$$\hat{\Gamma}_z^M = \hat{\Gamma}_0^M (\bar{\zeta} - \hat{\zeta}), \quad (28a, b)$$

$$\text{where } \hat{\Gamma}_0^M = O\left(r_o^4 \hat{\Sigma} \mathcal{B}_o^2\right) \approx 4 \times 10^{27} \text{ Nms},$$

for $\mathcal{B} = 0.5 \text{ mT}$. Here $\mathcal{B}_o^2$ is an average of $(B_r^N)^2$ over the CMB, and $\bar{\zeta}$ is defined by:

$$\bar{\zeta}(t) = \frac{1}{s^2 \hat{A}(s)} \int_0^{r_o} s^2 \hat{A}(s) \zeta(s, t) ds \quad (28c)$$

Perhaps unexpectedly, the boundary layer on the CMB described above reduces $\hat{\Gamma}_0^M$ by a factor of $\Sigma / (\Sigma + \hat{\Sigma})$, where Σ is the conductance of the boundary layer, defined by

$$\Sigma = \frac{1}{2} (1 + \varsigma) \sigma d_\eta = (1 + \varsigma) (\sigma / 2 \mu_0 |\omega|)^{1/2}, \quad (28d)$$

and $\varsigma = \text{sgn}(\omega)$. This gives $|\Sigma| \approx 3 \times 10^9 \text{ S}$, which is comparable with $\hat{\Sigma}$. Ignoring this factor, the magnetic interaction of mantle and FOC is governed by

$$\hat{C} d_t \hat{\zeta} = \hat{\Gamma}_0^M (\bar{\zeta} - \hat{\zeta}), \quad C d_t \bar{\zeta} = -\hat{\Gamma}_0^M (\bar{\zeta} - \hat{\zeta}), \quad (28e, f)$$

where $C = 9.08 \times 10^{36} \text{ kg m}^2$ is the polar moment of inertia of the solidly rotating FOC. These equations provide an estimate of the e -folding time, $\hat{\tau}_\eta$, taken by mantle conduction to kill $\hat{\zeta}$ and $\bar{\zeta} : \hat{\tau}_\eta = C \hat{C} / (C + \hat{C}) \hat{\Gamma}_0^M \approx 64 \text{ years}$. This is greater than the time taken by the waves to cross the core, which is $\tau_A = r_o / V_A \approx 5.6 \text{ years}$, for $\mathcal{B} = 2 \text{ mT}$.

If we take $\delta \hat{\zeta} \approx 3 \times 10^{-12} \text{ s}^{-1}$, as indicated by the LOD data of the first section above, Eq. 28e, f suggest that $\bar{\zeta} - \hat{\zeta} \approx (\hat{C} + C) \hat{\zeta} / C$ is about $2 \times 10^{-11} \text{ s}^{-1}$, so that $r_o (\bar{\zeta} - \hat{\zeta}) \approx 7 \times 10^{-5} \text{ m s}^{-1}$, which is less than, but comparable with, the inferred core surface flow. It also gives $\hat{\Gamma}_z^M \approx$

$8 \times 10^{16} \text{ Nm}$. This increases to the target torque if we take $\hat{\Sigma} = 1.2 \times 10^9 \text{ S}$, but that reduces $\hat{\tau}_\eta$ to 5.3 years, which is less than τ_A .

This highlights a difficulty that might be called the “magnetic coupling paradox,” and quantified by a quality factor:

$$\Pi = \hat{\tau}_\eta / \tau_A = (\mathcal{B} / \mathcal{B}_o)^2 (\mu_0 \hat{\Sigma} V_A)^{-1}. \quad (29)$$

There is a window for $\hat{\Sigma}$, that may be narrow or nonexistent, in which $\hat{\Gamma}_z^M$ is large enough to explain variations in LOD by torsional waves, but simultaneously is small enough to ensure that $\Pi > 1$ so that the waves are not over damped by mantle conduction. According to the admittedly imprecise, order of magnitude estimates made here, the window is nonexistent. For the target torque to be reached or exceeded, $\hat{\Gamma} \gtrsim 1.2 \times 10^9 \text{ S}$, but $\Pi > 1$ requires $\hat{\Gamma} \lesssim 1.1 \times 10^9 \text{ S}$. See also Dumberry and Mound (2008).

So far the existence of the SIC has been ignored, almost totally. We have however recognized that, for $s < r_i$, two Taylor cylinders exist, $\mathcal{C}^N(s)$ and $\mathcal{C}^S(s)$, in which $\zeta^N(s)$ and $\zeta^S(s)$ may be expected to differ. For simplicity, we assume here that they are equal. To evaluate $\tilde{\Gamma}_z$, it is necessary to link $\mathbf{b}$ to $\tilde{\mathbf{b}}$ across a boundary layer strongly influenced by Λ . An analysis of the boundary layer leads to (see RA12)

$$\tilde{b}_\phi = \mu_0 \tilde{\sigma} \tilde{d}_\eta |s B_r^N(\tilde{\zeta} - \tilde{\zeta})| \quad \text{on } r = r_i, \quad (30a)$$

where $\tilde{\zeta}$ is the angular velocity of the SIC, and $\tilde{d}_\eta = (\frac{1}{2} |\omega| \mu_0 \tilde{\sigma} i)^{-1/2} \approx d_\eta \approx 10 \text{ km}$. This leads to an expression for $\tilde{\Gamma}_z^M$, in which the main part that couples to the TC is

$$\begin{aligned} \tilde{\Gamma}_z^M &= \tilde{\Gamma}_0^M (\tilde{\zeta} - \tilde{\zeta}), \quad \text{where} \quad \tilde{\Gamma}_0^M \\ &= O(r_i^4 \tilde{\sigma} \tilde{d}_\eta \mathcal{B}_i^2); \end{aligned} \quad (30b, c)$$

cf. Eq. 28a, b. For $\mathcal{B}_i = 5 \text{ mT}$, $\tilde{\Gamma}_0^M \approx 2 \times 10^{29} \text{ Nms}$. This large torque acts on the SIC whose moment of inertia is less than $10^{-3} \hat{C}$. The coupling time, $\tilde{\tau}_\eta$, is therefore very much less than $\hat{\tau}_\eta$. Equations analogous to Eq. 28a, b give (for $\tilde{\sigma} = \sigma$)

$$\tilde{\tau}_\eta \approx \tilde{C} / |\tilde{\Gamma}_0^M| \approx 4 \text{ days}. \quad (30d)$$

This is the time taken for a mismatch between ζ and $\tilde{\zeta}$ to be wiped out by magnetic torques. Clearly the coupling between TC and SIC is substantial at frequencies of order ω_A . This supports the opinion, advanced several times in this review, that on semi-decadal time scales, the TC is effectively locked to the SIC in its rotation about Oz.

Synthesis

In this review we have analyzed the various ways in which Earth’s core is coupled to the mantle and have presented estimates of the amplitudes of these couplings in order to show which may plausibly explain the available LOD data. In our first section, we provide observational evidence for core-mantle coupling. We show that Earth’s rotation rate has a roughly semi-decadal time variability, such that the LOD fluctuates at the ms level. To explain these LOD fluctuations, an internal coupling must exist between the mantle and the core that provides torques of order 10^{18} Nm , which we named “the target torque.”

In the later text, we develop estimates of the strength of the viscous, topographic, gravitational, and electromagnetic torques. Only the viscous torque, Γ_z^V , appears to be too weak to explain the LOD signal. This is true even when we allow for the enhanced coupling that turbulence can provide.

The topographic torque on the mantle, $\hat{\Gamma}_z^T$, is created by core flow interacting with bumps on the CMB. In analyzing $\hat{\Gamma}_z^T$, it became clear that exchange of angular momentum with the SIC is significant. Order of magnitude arguments showed that potentially the largest part of $\hat{\Gamma}_z^T$ is $\hat{\Gamma}_{a,z}^T$, which is produced by the gravitational field of density anomalies in the mantle and possibly SIC, including bumps on their surfaces. This part of $\hat{\Gamma}_z^T$ is therefore intimately related to the gravitational torque $\hat{\Gamma}_z^G$. When the two are treated together as $\hat{\Gamma}_{a,z}^{G+T}$, there is an equal but opposite torque, $\hat{\Gamma}_{a,z}^{G+T}$ on the SIC. Gravitational oscillations (Buffett 1996) occur when the system is perturbed from a state of minimum gravitational energy in which $\hat{\Gamma}_{a,z}^{G+T} = \tilde{\Gamma}_{a,z}^{G+T} = 0$. An oscillation period of $\tau^G = 4.1 \text{ years}$ was derived. If, as seems likely, strong magnetic coupling exists between the tangent cylinder (TC) and the SIC, the gravitational oscillation period increases to $\tau_{TC}^G = 8.9 \text{ years}$.

The remaining part of $\hat{\Gamma}_z^T$ is $\hat{\Gamma}_{c,z}^T$, and is produced by core convection. Its importance is uncertain. From what is known today, $\Gamma_{c,z}^T$ may be 0 Nm or may exceed the target torque (cf. Kuang and Bloxham 1997; Hide 1998; Jault and Le Mouél 1999; Kuang and Chao 2001).

A simple model of torsional waves traversing FOC can explain oscillations of period, $\tau \approx 6 \text{ years}$, but there is a paradox: The target torque cannot be attained by magnetic coupling between the waves and the mantle unless a dimensionless “paradox parameter,” Π , defined in Eq. 29, is large enough. If this parameter is too large, however, the waves are damped out before they can cross the core. Whether the core can evade the paradox seems uncertain.

The topographic, gravitational and magnetic torques all have significant uncertainties in their amplitudes, but the target torque falls within these uncertainties, i.e., conceivable any of them could explain the semi-decadal LOD signals. The coupling processes may be convolved. The recent model of

Buffett et al. (2009) allows for this, but argues that the gravitational torque dominates. In contrast, Gillet et al. (2010) infer that torsional oscillations in the FOC can explain the LOD observations without strong gravitational coupling. Improvements in data and modeling of Earth's rotation (e.g., Gross 2009), the geomagnetic field (e.g., Hulot et al. 2002; Jackson 2003), core seismology (e.g., Dai and Song 2008), and the time-variations in the gravity field (e.g., Velicogna and Wahr 2006; Dumberry 2010) will all prove important in testing these core-mantle coupling arguments.

This review has focussed on explaining variations in LOD owing to internal coupling between the mantle and core. This coupling produces changes primarily in the axial angular rotation rate, Ω_z , on semi-decadal time scales. Detailed measurements now exist of variations in Earth's full rotation vector on many time scales (e.g., Gross 2007), with the different directional components providing information on different geophysical phenomena (e.g., Mathews et al. 2002). Furthermore, rotation vector and magnetic field measurements now exist for other planets (e.g., Margot et al. 2007; Uno et al. 2009), and will improve in quality in the coming decades. Such measurements will allow the development of models of deep interior structure and dynamics in planetary bodies throughout the solar system (e.g., Tyler 2008; Noir et al. 2009; Goldreich and Mitchell 2010).

Crustal Reflectivity (Oceanic) and Magma Chamber

Satish C. Singh

Laboratoire de Géoscience Marines, Institut de Physique du Globe de Paris, Paris, France

Synonyms

Melt lens; Spreading center and ridge

Definition

Axial magma chamber (Melt lens) is a thin melt lens observed at ocean spreading centers.

Layer 2A or *Lava* is the top layer of oceanic igneous crust.

Layer 2B is a dike sequence and lies above the axial melt lens.

Layer 3 (gabbro) forms the lower oceanic crust.

Moho is a boundary between the crust and mantle.

Pg is a seismic ray that travels through the crust.

PmP is a reflection from the crust–mantle boundary.

Pn is a ray that travels in the upper mantle.

Tomography is a technique to image the velocity structure of the earth.

Introduction

Over 70% of the earth's crust is formed by the cooling and crystallization of melt at ocean spreading centers, which represent over 55,000 km of chains of volcanoes in the middle of the oceans, called mid-ocean ridges. At ocean spreading centers, the oceanic plate separates causing the mantle to move upward, reducing the pressure and causing the melting of the mantle. Since the newly formed melt is lighter than the surrounding mantle material, it moves upward toward the surface of the earth. Part of the melt is erupted on the seafloor as lava, which cools very rapidly forming a cap of solid extrusive layer, also known as Layer 2A (Fig. 1). As there is a significant amount of water present at mid-ocean ridges, the water circulates deep in the crust. Therefore, the melt stays mainly in the middle of the crust and erupts along thin dikes. When these dikes are cooled and crystallized, they form a thick intrusive layer or Layer 2B. Below the dikes, the melt could reside for a long period, forming a steady state melt lens, called axial melt lens or axial magma chamber (AMC). The magma cools and crystallizes in this melt lens, forming a crystalline lower crust. The melt lens forms the lower limit for further penetration of water, and therefore, partial melt is generally present beneath the melt lens down to the crust–mantle boundary. Sometimes hot melt ascending from the mantle may get injected in this partially molten region. Based on this basic process, the oceanic crust is divided into three layers, lava (extrusive), dikes (intrusive), and gabbroic crust. The relative thicknesses of these layers depend on the spreading rate, which can vary from a few millimeters up to 200 mm per year.

Based on the spreading rate, mid-ocean ridges are divided into four groups: fast, intermediate, slow, and ultraslow. East Pacific Rise (EPR) is a fast spreading center, where the spreading rate varies from 70 to 180 mm per year (Fig. 2). Juan de Fuca Ridge and Valu Fa Ridge are intermediate

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 1 Classical model of the oceanic crust. Layers 2A and 2B form the upper crust whereas the gabbro layer corresponds to the lower crust

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 2 Major spreading centers on the earth. JFR, Juan de Fuca Ridge; VFR, Valu Fa Ridge; CIR, Central Indian Ridge. The rectangles indicate the positions of data/results shown in this entry: 1, Lucky Strike Segment at Mid-

Atlantic Ridge (Figs. 5, 7, 9, and 12); 2, 9° N East Pacific Rise (Figs. 8, 11, and 14); 3, 14° S East Pacific Rise (Figs. 6, 10, and 13); and 4, Wharton basin (Figs. 15 and 16)

spreading centers, where the spreading rate varies from 55 to 70 mm per year. Mid-Atlantic Ridge and Central Indian Ridge are slow spreading centers with spreading rates of 20–55 mm per year. South-West Indian Ridge and Gakkel Ridge are ultraslow spreading centers with spreading rates of less than 20 mm per year. The melt production depends on the spreading rate and, therefore, the crustal thickness also varies from 3.5 to 8 km, with an average thickness of 6 km.

Methods

There are two main methods to study the oceanic crustal structures: seismic refraction or tomography and reflection methods. In seismic refraction method, a set of ocean bottom seismometers (OBS) are placed on the seafloor and an array of air guns is used to generate acoustic energy that travels through water column into the crust and mantle and is recorded on OBS (Fig. 3). There are three types of waves that arrive on an OBS: waves that travel in the crust (Pg) and the mantle (Pn) and waves reflected from the crust–mantle boundary, Moho (PmP). The travel times of arrivals of energy on these OBS are used to determine the velocity structure of the crust and upper mantle. Since OBS are small in numbers,

they are placed 5–20 km apart on the seafloor, and hence provide a very large-scale (5–10 km) velocity structure of the crust. Since the compressional (P) waves travel fast, they arrive first on OBS, and hence mainly P-wave velocities are estimated using OBS data. However, sometimes secondary (S) arrivals, converted phases Ps, are recorded on these OBS and provide information on S-wave velocity.

Seismic reflection method is most commonly used to obtain crustal reflectivity. A streamer containing pressure sensors (hydrophones) is towed behind a vessel recording seismic energy generated by an array of air guns as the vessel moves at 4.5–5 knots (Fig. 3). The length of the streamer varies from a few hundred meters up to 15 km (Singh et al. 2009), and hydrophones are generally spaced at 12.5 m. For crustal imaging the air gun shot spacing is ~50 m. Depending upon the target depth, the recording length varies from 10 to 20 s (20–60 km depth). This technique is routinely used for oil and gas exploration, and has become a standard technique for crustal studies. There are standard tools to analyze these data. Since the source receiver distance is small as compared to the depth of the target, the data are initially presented as a function of time, and then are depth-converted using velocities obtained from the OBS study or from other sources.

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 3 Schematic diagram showing the seismic reflection and refraction survey to study the oceanic crust. Red star indicates the air gun source.

OBS, ocean bottom seismometers; Pg, crustal arrival; Pn, mantle arrival; and PmP, reflection from the crust–mantle boundary. Red ellipse indicates melt lens

Crustal Structure at Fast Spreading Centers

Based on seismic refraction and reflection studies at fast spreading centers and on ophiolites from Oman, the crust at fast spreading centers is considered as a layer cake and is divided into three distinct layers: Layer 2A (pillow lava), Layer 2B (dike sequence), and Layer 3 (gabbro) (Fig. 4). The velocity in Layer 2A varies from 2.5 to 4.5 km/s, that in Layer 2B from 4.5 to 6 km/s, and in gabbro from 6 to 7 km/s. On the ridge axis, a magma chamber is generally present between the dike and the gabbro layer.

The structure of Layer 2A is inferred either using the velocity from OBS study or from the reflection method. The boundary between Layer 2A and 2B is not sharp but there is a high velocity gradient where the velocity increases from 2.5 to 4–4.5 km/s in a thin transition zone, which leads to three arrivals (triplication) from Layer 2A (Fig. 5). However, since the first arrival tomography is performed on OBS data, spaced at 5–10 km distance, one can only get a smooth velocity of the crust. Therefore, a velocity contour of 4.5 km/s is generally used at the base of Layer 2A (Fig. 4, *dashed curve*).

In seismic reflection data, the triplication from the Layer 2A/2B boundary lies in a narrow offset range at intermediate offsets, depending on the water depth and the thickness of Layer 2A (Fig. 5) (Harding et al. 1993; Seher et al. 2010a). Since the cusp of triplication has strong amplitude, it can be used to image the base of Layer 2A, and leads to a very nice image of Layer 2A. Since the energy lies in a limited offset range, the two-way travel time for these images varies depending on the velocity used for stacking. This becomes particularly important when the thickness map needs to be prepared from 3D seismic reflection data or compared along long profiles. In order to objectively compare Layer 2A

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 4 Average one-dimensional velocity of oceanic crustal layers and mantle (solid brown line). Thin dashed line indicates velocity determined using tomographic type techniques

thickness, a constant velocity that provides the best image of Layer 2A is used to stack Layer 2A arrival and the two-way travel time is converted into depth using the tomographic velocity obtained using either OBS data or streamer tomography (Seher et al. 2010a).

Plot Triplication

Figure 6 shows the image of Layer 2A obtained along the southern East Pacific Rise (Kent et al. 1994). The thickness of the layer varies from ~200 m on the ridge axis and increases to 600 m off-axis (Kent et al. 1994; Harding et al. 1993). The thickening of Layer 2A off-axis could be associated with the

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 5 Seismic reflection from the Lucky Strike Segment of Mid-Atlantic Ridge showing triplication (dashed curve) from Layer 2A/2B boundary. (Modified from Seher et al. 2010a)

accumulation of lavas away from the ridge axis. On slow spreading ridges, Layer 2A could be up to 1 km thick (Singh et al. 2006a; Seher et al. 2010a). Instead of thickening of Layer 2A away from the spreading center, its thickness decreases, which could be due to thinning by stretching (faulting) of the crust (Fig. 7). In fact, the thinnest (300 m) Layer 2A at the Lucky Strike segment is observed near the Median bounding faults (Seher et al. 2010a).

There is still debate about the causes of Layer 2A reflection: it could be due to pillow lava and dike boundary as shown in Fig. 4 or due to alteration front associated with hydrothermal circulation or pressure collapse boundary (Christeson et al. 2007).

Below Layer 2A, the velocity increases from 4.5 up to 6 km/s, corresponding to dike sequence, below which a magma chamber reflection might be present. The thickness of the dike sequence is ~1.5 km on a fast spreading center (Vera et al. 1990) and up to 2 km on a slow spreading center (Seher et al. 2010b).

Axial Magma Chamber (Melt Lens)

On a fast spreading center, the axial magma chamber (AMC) reflector marks the boundary between the upper crust (lava and dikes) and the lower crust (gabbro). It is observed along a significant part of the fast spreading axis at 1.5–2 km below the seafloor. The width of the AMC varies from a few hundred meters to 4.5 km (Kent et al. 1993). The largest melt lens is observed beneath 9° N overlapping spreading center at the

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 6 Seismic reflection image of Layer 2A and axial magma chamber at 14° S East Pacific Rise (Position 3 in Fig. 2). (From Kent et al. 1994). The Layer 2A thickness varies from 200 m on the ridge axis to 400 m off-axis

East Pacific Rise (Kent et al. 2000; Singh et al. 2006a) (Fig. 8). Recently, Canales et al. (2009) have imaged an off-axis melt lens. A 3D seismic reflection study of the 9° N EPR suggests that there might be an extensive presence of melt sills off-axis (Carton et al. 2009).

The AMC have also been observed beneath intermediate spreading centers such as Juan de Fuca Ridge (Canales et al. 2006) and Valu Fa Ridge (Collier and Sinha 1990). They are generally observed about 3 km below the seafloor. It has been difficult to image AMC reflection on slow spreading ridges, which has been due to strong scattering on the seafloor and complex 3D bathymetry. Using 3D seismic reflection technique, Singh et al. (2006b) discovered AMC beneath the Lucky Strike segment of the Mid-Atlantic Ridge (Fig. 9). The AMC is about 3 km wide and 7 km long at ~3 km below the seafloor.

The thickness of the melt lens is difficult to determine. Forward modeling of seismic reflection data from 9° N at EPR suggests that it could be 50–100 m thick (Kent et al. 1993). Seismic full waveform inversion of data from two locations at the EPR suggests that it should be 50–60 m thick (Collier and Singh 1997; Singh et al. 1998, 1999). Using full waveform of seismic reflection data from 14° S at EPR, Singh et al. (1999) found that a 60 m thick melt lens is overlain by a 60 m thick solid roof and underlain by a 200 m thick solid floor. Above the roof layer, they find a 200 km thick low velocity layer, which they associate with the presence of hydrothermal circulation (Singh et al. 1999) (Fig. 10). The roof layer could be the transition zone between the hot melt (1,200 °C) below and the hydrothermal layer (400 °C) above.

The presence of a solid floor suggests that magma cools and crystallizes in the melt lens and forms the solid floor.

Crustal Reflectivity (Oceanic) and Magma Chamber,

Fig. 7 Seismic reflection of Layer 2A beneath the Lucky Strike volcano at slow spreading Mid-Atlantic Ridge (Position 1 in Fig. 2). F1 indicates an active fault. Layer 2A is thick beneath the ridges and thin beneath the fault

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 8 Seismic reflection image of axial magma chamber (AMC) and Moho reflection at 9° N overlapping spreading center at the East Pacific Rise (Position 2 in Fig. 2). (Modified from Singh et al. 2006a)

Using 3D seismic reflection data, we can image the base of the melt lens. Here the melt lens is about 4.5 km wide and could be up to 250 m thick (as compared to 50–100 m observed elsewhere). This could be due to its very large size (4.5 km) and the presence of low velocity underneath it (Bazin et al. 2003). Singh et al. (2006a) suggest that up to 40% melt could be present between 1.5 and 6 km depth, making it the largest observed melt lens in the crust observed on the earth so far (Fig. 11).

Using full waveform and partial stacking technique of seismic reflection data, Singh et al. (1998) show that the melt along 14° S EPR consists of 2–4 km long pure melt zones at 15–20 km interval along the ridge axis (Fig. 10). They associate pure melt region where the shear wave velocity is nearly zero and partial melt zone where the shear wave velocity is nonzero (Taylor and Singh 2002). They suggest that a pure melt region corresponds to fresh supply of magma from the mantle and a partial melt region corresponds to

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 9 Axial magma chamber reflection image from the Lucky Strike Segment of the Mid-Atlantic Ridge (Position 1 in Fig. 2)

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 10 Full waveform inversion results at two different locations along the 14° S EPR (Position 3 in Fig. 2). Inversion results show the presence of 60 m AMC, 60 m thick roof, and 200 m thick floor of the AMC. It also shows a hydrothermal layer above the roof of the AMC. The result on the

left panel corresponds to a partial melt region (less than 50% of liquid melt) whereas that on the right corresponds to a pure melt (more than 80% of liquid) region. The depth is from the seafloor. (Modified from Singh et al. 1999)

cooled and crystallized state of melt lens. They also find that a pure melt region is associated with hydrothermal activities on the seafloor, linking the supply of magma from the mantle with hydrothermal circulation on the seafloor. In order for the

melt lens to be in steady state, it would require a supply of magma from the mantle every 30 years as it will take 50 years to completely solidify a 50 m thick melt lens (Singh et al. 1999).

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 11 Seismic reflection image showing the top and bottom of the axial magma chamber at 9° N EPR (Position 2 in Fig. 2)

Lower Crust

So far, no other crustal melt lenses have been observed beneath the axial melt lens. Therefore, only tomographic methods using OBS data are used to determine the velocity structure of the lower crust. Using two-ship expanding spread profile, Vera et al. (1990) and Harding et al. (1989) found that the velocity in the lower crust (5.5–6 km/s) on-axis was lower than that off-axis (6.8–7 km/s), which suggested the presence of partial melt in the lower crust. Using 3D tomography technique, Toomey et al. (1990) and Dunn et al. (2000) showed the presence of low velocity in the lower crust, suggesting the presence of partial melt. Singh et al. (2006b) found a large anomaly in two-way travel time between the Moho reflection and AMC and suggest that up to 40% of melt might be present in the lower crust (Fig. 8). A low velocity anomaly has also been observed beneath the Lucky Strike segment of the Mid-Atlantic Ridge beneath the melt lens (Seher et al. 2010c; Singh et al. 2006b). These results suggest that partial melt is present in the lower crust beneath the melt lens (Fig. 12).

Based on the study of Oman ophiolite, Kelemen et al. (1997) and Boudier et al. (1996) suggested that the lower crust is formed by injection of melt sills in the lower crust instead of cooling and crystallization of magma in the upper crustal melt sill. However, no melt lenses have been imaged in the lower crust so far, even using 3D seismic reflection technique (Singh et al. 2006a), which suggest that the melt in the lower crust must be in small pockets, not in large melt sills.

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 12 Tomographic results from the Lucky Strike Segment of the Mid-Atlantic Ridge (Position 1 in Fig. 2) showing melt lens (red line), low velocity in the lower crust, and Moho across the ridge axis. The inverse triangle is the center of the ridge axis. (Modified from Seher et al. 2010c)

Oceanic Moho

The Moho is a boundary between the crust and mantle, where the velocity changes from 6.8–7.0 km/s to 7.8–8.1 km/s. For a sharp boundary, a clear Moho reflection is observed. However, the Moho is not just a simple boundary. Kent et al. (1994) identified three types of Moho reflection: (1) Impulsive Moho where a clear single reflection is observed (Fig. 13), (2) Diffuse Moho where reflection from Moho is patchy, and (3) Shingled Moho where reflection is shingled.

Moho reflections are generally observed away from the spreading center, not beneath the melt lens. This is because the upper crustal melt lens and associated lower crustal melt would attenuate seismic energy and hence, it would be difficult to image Moho using conventional seismic reflection techniques. Secondly, it was accepted that Moho is formed away from the ridge axis. However, using 3D seismic reflection technique, Singh et al. (2006a) have imaged Moho beneath the wide axial melt lens (Fig. 14), suggesting the Moho is formed at zero age.

Moho reflections are observed ~2 s two-way travel time below the seafloor. The average crustal velocity is about 6 km/s, and hence the average crustal thickness is about 6 km. However, Singh et al. (2011) have observed Moho reflection 1.3 s below the seafloor offshore NW Sumatra, where the crust was formed at the fast spreading Wharton ridge about 55 Ma ago. If we assume an average velocity of 6.0 km/s, which means at the crust there is only 3.5 km thick, it would be the thinnest crust ever observed in a fast spreading environment (Fig. 15).

Since there is a positive velocity contrast at the crust–mantle boundary, large amplitude critical angle reflections

Crustal Reflectivity (Oceanic) and Magma Chamber,

Fig. 13 Different types of reflection for Moho boundary observed at Southern East Pacific Rise (Position 3 in Fig. 2) (Kent et al. 1994). Top: Shingled Moho, Middle: Diffuse Moho, Bottom: Impulsive Moho

Crustal Reflectivity (Oceanic) and Magma Chamber,

Fig. 14 Seismic reflection image of Moho beneath the melt lens at the 9° N East Pacific Rise (Position 2 in Fig. 2)

(PmP) are generated that arrive at large offsets (15–30 km), and are recorded on OBS. These data are then used to map the Moho structure. However, there are two problems in using arrival times of PmP arrivals. The velocity gradient in the lower crust is very small or close to zero, and therefore rays that sample the lower crust do not turn in the lower crust making it difficult to estimate velocity in this zone. Since the arrival time of PmP arrival depends on the velocity in

the crust, particularly the lower 3 km of the crust, it is difficult to estimate both the velocity in the lower crust and the Moho structure. Since the velocity in the lower crust can be approximated to a large extent ~ 6.8 km/s, these data provide a reasonable constrain on the Moho structure, and are routinely used. Secondly, the OBS spacing is generally 5–20 km and the lateral resolution of the Moho structure is very poor.

Crustal Thickness

Once we determine the velocity in the crust and Moho structure, we can estimate the crustal thickness. So far, most of the crustal thickness estimations are based on wide-angle seismic studies, and there are significant uncertainties in crustal thickness estimations for the reason explained above. However, combined analyses of seismic reflection, refraction, and gravity data suggest that wide-angle estimation of the crustal thickness can be very reliable.

The crust formed at fast spreading centers is generally uniform and 6 km thick (White et al. 1992; Eittreim et al. 1994) but some variations (5–8 km) have been observed recently (Canales et al. 2003; Singh et al. 2006a; Barth and Mutter 1996). There is no significant crustal thickness variation across the fracture zone in a fast spreading environment, where it is also 5.5–6 km thick (Van Avendonk et al. 2001). The crust formed at slow spreading centers is generally thick at the center of the segment (6–7 km) and thin at segment ends (4–5 km) (Barclay et al. 1998; Seher et al. 2010b). The crust beneath fracture zones in a slow spreading environment is generally thin (3–4.5 km) (Detrick et al. 1993). The thinnest crust (3.5–4.5 km) is formed at ultraslow spreading centers (Jokat and Schmidt-Aursch 2007). These observations

suggest that the thickness of the crust depends on the spreading rate and melt distribution in the crust. On the other hand, thicker crusts are found beneath large igneous provinces, across hotspot tracks or at the interaction of plume and ridges, which are believed to be formed by higher mantle temperatures due to the presence of a plume (e.g., Parkin and White 2008; Watts et al. 1985; Charvis et al. 1999; Grevenmeyer et al. 2001). For example, the crust beneath Iceland could be up to 30 km thick, and beneath La Reunion Island it is 13 km (Charvis et al. 1999).

However, anomalously thin crust has been reported. A 5 km thick crust is observed near the South American trench (Grevenmeyer et al. 2007) and in the area of IODP Hole 1256 (Hallenborg et al. 2003) for crusts formed at the EPR about 20 Ma. Rodger et al. (2006) found an ultrathin crust (4 km) that was formed near the central MAR about 85 Ma ago, which they associate to be due to a reduction in the spreading rate from slow to ultraslow. The crustal study at ODP holes 504B also found thin crust (5 km), which Collins et al. (1989) associate to be due to depleted mantle. Singh et al. (2011) have observed ultrathin crust (3.5–4.5 km) in the Indian Ocean (Fig. 15) that was formed at fast spreading Wharton center 55 Ma ago, which they associate to be due to the interaction of the Kerguelen plume with the Wharton

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 15 Seismic reflection image of extremely thin crust in the Indian Ocean (Position 4 in Fig. 2). (Modified from Singh et al. 2011)

Spreading center due to channeling of the cold lithosphere around a plume and its interaction with the spreading center.

Upper Mantle

The velocity in the upper mantle is generally determined using rays that turn below the Moho, which are called Pn arrivals. The velocity in the mantle beneath ridge axis is ~ 7.6 – 7.8 km/s and is 8–8.1 km/s away from the ridge axis (Vera et al. 1990; Harding et al. 1989). An extensive 3D tomography and undershoot experiment were carried out at 9° N EPR. Using these data, Dunn et al. (2000, 2001) obtained a symmetric low velocity anomaly below the Moho in the mantle. Using the same data and some new data Toomey et al. (2007) found asymmetric low velocity anomaly at 10 km away from the ridge axis. There are serious problems with these results. First, the crustal thickness in this area varies from 6 to 8 km. Secondly, the velocity anomaly depends on the background velocity used during the inversion. Dunn et al. (2000) use a starting mantle velocity of 8.2 km/s whereas one year later Dunn et al. (2001) use 7.6 km/s. Although the crustal thickness is up to 8 km (Canales et al. 2003), Dunn et al. (2001) interpret velocity at 7 km below the seafloor; the part of the anomaly could be due to crustal variations. Toomey et al. (2007) show that the ray only penetrates down to 8 km below the seafloor but interpret the velocity at 9 km below the seafloor. These conflicting results and the inaccuracy in inversion led Singh and Macdonald (2009) to suggest that these results are not reliable. The only robust solution we have is that the velocity in the mantle is ~ 7.6 – 7.8 km/s below the ridge axis and 8–8.1 km/s away from the ridge axis (Vera et al. 1990; Harding et al. 1989). However, it is possible that melt sills get trapped in the mantle as shown by Nedimovic et al. (2005) and may lead to a low velocity anomaly in the mantle.

Faults in the Oceanic Crust and Upper Mantle

Along with magmatic process, tectonic processes also play an important role in shaping the oceanic crust. Singh et al. (2006b) have shown that median valley bounding faults could be imaged down to 3 km, close to the melt lens. They also found extensive faults above the melt lens. It is possible that some of these faults penetrate down to the crust–mantle boundary (Dusunur et al. 2009).

In a subduction zone environment, there are two forces that act on the incoming oceanic plate: plate bending leading to normal faulting and compressive forces leading to thrust faulting. Water can enter into the mantle leading to serpentinization of the oceanic mantle. Normal faulting down to

Crustal Reflectivity (Oceanic) and Magma Chamber, Fig. 16 Seismic reflection of deep penetrating faults in the mantle in the Indian Ocean (Position 4 in Fig. 2)

5–8 km below the Moho, related to bending of the subducting plate and the associated serpentinization, has been reported for the Central American trench (Ranero et al. 2003). Faults have also been imaged in the mantle offshore Sumatra down to 35 km depths (Fig. 16) suggesting that a significant part of the oceanic lithosphere is involved during oceanic earthquakes.

Summary

The reflectivity of the oceanic crust and axial magma chambers at ocean spreading centers are described in detail using real seismic images. The oceanic crust consists of three distinct layers: Layer A is 200–1,000 m thick and consists mainly of pillow lavas. Layer B is 1–2 km thick and consists mainly of cooled basalts in dikes. Layer 3 is 2–3 km thick and is formed by the cooling and crystallization of magma in the melt lens. Axial melt lens has been imaged on fast and intermediate spreading centers and recently on a slow spreading center (Singh et al. 2006b). Melt lenses are 50–60 m and have a roof and a floor. Between the melt and Moho, lower crust, partial melt is generally present. The oceanic crust is about 6 km thick, which could vary from 3.5 to 8 km. The

P-wave velocity in the mantle lie between 7.6 and 8.1 km/s, but the detailed nature of the oceanic mantle is poorly constrained and requires further investigations. Faults due to earthquakes have been observed down to 35 km depth.

Curie point

Definition

A rock containing magnetic minerals loses its permanent magnetism when heated up to a critical temperature, referred to as Curie temperature or Curie point, T_c . On the atomic level, below T_c , the magnetic moments are aligned in their respective domains, and even a weak external magnetic field results in a magnetization. As the temperature increases to T_c and above, fluctuations due to the increase in thermal energy destroy that alignment, and the rock becomes paramagnetic.

Magnetic Minerals and Curie Temperature

The most important magnetic rock-forming minerals are oxides of iron and titanium, and their compositions can be represented in the FeO-TiO₂-Fe₂O₃ ternary diagram. Among the three major solid-solution series identified in this system, the titanomagnetite series, Fe_{3-x}Ti_xO₄ (with $0 \leq x \leq 1$), plays a major role in controlling rock magnetism (Stacey 1992). Above 600 °C there is a continuous solid solution in the two-component series magnetite (Fe₃O₄) and ulvöspinel (Fe₂TiO₄), which upon cooling is restricted toward the end-members. Magnetite, the most abundant and strongly magnetic mineral, is of ferrimagnetic type, i.e., neighboring magnetic moments are aligned antiparallel, as in antiferromagnetism, but unequal numbers or strengths, thus giving a net magnetization.

There are many other magnetic minerals, but they are rare (iron sulfide), unstable (maghemite), or having a weak spontaneous magnetization due to the canting of its equal and nearly opposite atomic moments (canted antiferromagnetism), as hematite occurring in sedimentary rocks often in solid solution with ilmenite.

Variation of Curie temperature with titanium substitution in the titanomagnetite series is approximately given by $T_c = 580 (1 - 1.26 x)$. In pure magnetite, T_c is 575–585 °C, but titaniferous inclusions can reduce T_c , which approximates room temperature for $x = 0.77$ (Hunt et al. 1995). Saturation magnetization is also a function of temperature, and it disappears above T_c ; at room temperature it decreases from 90 to 92 A m² kg⁻¹ for $x = 0$ to about zero for $x = 0.8$. Because Ti⁴⁺

has no unpaired spins, the saturation magnetization decreases with increasing x (Alva-Valdivia and López-Loera 2011). The cell dimensions increase with increasing x . As a result of the increased cell dimension, there is a decrease in Curie temperature.

T_c undergoes a small increase with pressure. At the boundary between the crust and the mantle (or Moho), the T_c increase should be no more than a few degrees of the experimental values at normal pressure.

Geomagnetic Implications

There is a connection between the anomalies of geomagnetic field and the temperature-depth distribution, since rock magnetization is strongly affected by temperature variations. The rocks lose their magnetization at a depth where the temperature is greater than T_c and, consequently, their ability to generate detectable magnetic anomalies disappears. By transforming magnetic anomaly data into the Fourier domain and analyzing their spectra, it is possible to infer the depth of the magnetic layer bottom (MLBD), i.e., where magnetic rocks are replaced with nonmagnetic material. Its comparison with information about thermal state of the Earth's crust can provide interpretation for both the magnetic source distribution and the Curie temperature.

Chiozzi et al. (2005) gave an example of MLBD determination and its relation with Moho depth, thermal structure, and geothermal flow in Central and Southern Europe (Table 1). MLBD corresponds to the Moho in the Variscan units, and the expected temperature is close to T_c of magnetite. Beneath the Alpine units, the magnetic layer bottom is shallower than the Moho and corresponds to temperature, as inferred from the geothermal flow, of 550 °C, indicating the presence of Ti. In the Ligurian basin, the temperature at the MLBD minimum depth is of 570 °C, hence compatible with the Curie point of magnetite. However, this depth is slightly larger than the Moho. Like observed in some oceanic regions (Counil et al. 1989), this might mean that the uppermost part of the mantle has magnetization.

Curie Temperature, Table 1 Moho depth, depth and temperature of magnetic layer bottom, and geothermal flow of main tectonic units in Central and Southern Europe

Tectonic unit	Moho depth (km)	Magnetic layer bottom		Geothermal flow (mW m ⁻²)
		Depth (km)	Temperature (°C)	
Variscan units (Central Europe, Corsica-Sardinia block)	29–33	29–33	540–580	60–70
Alpine units (Alps, Apennines, Molasse and Po basins)	25–50	22–28	500–600	50–80
Ligurian basin	17–24	20–24	570–650	80–100

Definition

Scientific Drilling	Applying drilling methods developed in the hydrocarbon and mineral exploration industry to dig holes and retrieve samples of rock and fluid for scientific, not-for-profit purposes.
Deep Scientific Drilling	Drilling for scientific research goals beyond near-surface geological and shallow groundwater exploration to depths greater than several hundred meters subsurface, through land, sea ice, or below the sea/lake floor.

Introduction

Geoscientific insight into the deep Earth is mostly based on observations from the surface, indirect evidence through deep geophysical investigations or, increasingly, modeling. However, several critical Earth system processes and records of environmental and paleoclimate change are difficult to observe from ground level only. Hence, despite the great progress achieved in solid Earth science of the past decades, truly ground-truthed knowledge of the dynamics of Earth's crust is limited.

Today, direct access to the interior of the Earth's crust is still confined almost exclusively to sedimentary basins where hydrocarbon resources are recovered through deep industry-financed wells, if typically shallow exploration and mining for groundwater and minerals are neglected. Deep

drilling for mainly scientific reasons has so far remained a relatively rare exception because the very high cost of drilling is a challenging barrier in the design of research projects. Nevertheless, this threshold can be overcome if societal interests are pressing, if political and financial support is gained, and typically if international long-term cooperation is achieved. A small number of international Earth science programs devoted to scientific drilling have been established with widely agreed-upon strategic scientific goals, international co-funding, and a necessary minimum of infrastructure and operational capabilities. While the overarching research goals are almost identical, the drilling programs are separated, based on largely technological grounds, into oceanic (Integrated Ocean Discovery Program 2011) and continental (International Continental Scientific Drilling Program, Horsfield et al. 2014).

Goals of Scientific Drilling

The international programs for scientific drilling address topics of broad international interest which can contribute significantly to solving important Earth science themes of high societal relevance (Fig. 1). The research themes of these programs can be summarized in three overarching branches:

- The evolution and dynamics of Earth's crust and lithosphere, especially in subduction zones and orogenic belts, with special emphasis on the physicochemical background of geological hazards such as earthquakes, volcanic eruptions, landslides, and meteorite impacts.
- Environmental, climate, and paleoceanographic changes as recorded in geological archives of sediments in the oceans, in lakes, in ice shields and in other depositional environments, including the resulting biological consequences, as well as the exploration of the widely unknown microbial biosphere living at depth.

Deep Scientific Drilling, Fig. 1 Sketch of research themes addressed by major international scientific drilling programs

- Basic science of unconventional resources such as methane hydrates or geothermal energy, and of novel utilization of the deep underground environment such as CO₂-sequestration.

This chapter addresses mainly the first topic on lithospheric dynamics, hazard, and evolution of the Earth because most deep scientific drilling projects are dealing to a large extent with questions about internal forcing, whereas climate, environmental, and subsurface biosphere research primarily employs shallow drilling techniques.

Drilling, Sampling, and Monitoring Techniques

A standard in most deep drilling operations (e.g., hydrocarbon exploration) is the rotary drilling technique. A cutting bit is lowered into the ground on a steel tube rotated through a rotary drive in a drilling derrick. The propelled drill string consists of connected pipe elements through which a drilling fluid is pumped down the well. The drill mud, usually water with clay minerals and other added solids to provide viscosity, cools the bit and flushes out chips of the destroyed volume of rock (drill cuttings) to the surface through the annulus between the borehole wall and the drill string. The weight-on-bit is controlled through adjusted variable lifting of the string which is pulled down and kept in tension by heavy

weight sections of drill pipe installed right above the drill bit. The drilling progress is supported by extending the string in the derrick with additional sections, or stands, of pipe. When drilling from a barge, ship or floating platform, the annulus extends only to the sea/lake floor, so mud and cuttings do not return to the drill rig. In this setting, drilling can be performed with water in place of drilling mud, and cutting spilling out on sea or lake bottom around the well. However, if pressure control and mud return is required, an outer second pipe, a so-called “riser,” is put in place, so the mud and cuttings can be pumped back to the deck. Furthermore, in waves or swell, a heave compensation device is required to ensure constant weight-on-bit. Drilling through tidally lifted ice necessitates defrosting of the pipe in the ice section. Figure 2 summarizes basic drilling methods and important elements used in scientific drilling.

In normal rotary drilling technique, coring is performed with a hollow core bit that leaves a central column of rock that slides into the pipe while drilling progresses. After a few meters of coring, the whole assembly has to be pulled back out of the hole (called “pipe tripping”) to get the core to surface. In scientific drilling projects, by contrast, continuous coring is often desirable. To avoid time-consuming pipe tripping runs, wireline coring techniques are applied. An inner core barrel is lowered through the drill string and latches in above the core bit, collecting and holding the drilled-out rock column, and is finally retrieved by a winch-drawn steel cable, obviating the need for a complete pipe round trip with each

Deep Scientific Drilling, Fig. 2 Principle technical components and styles of drilling operations in different environments

core. The actual formation-cutting method varies depending on the type of rock or sediment present. Typically, thin-kerfed diamond core bits with high-rotation speed are used for hard rock drilling, roller cone abrasion bits are used for softer sedimentary rock, and nonrotating sharp edged hollow metal pistons of several meters length are hydraulically shot (forced) into soft sediments to collect cores and advance the borehole (Fig. 3).

After research wells are drilled, in situ measurements and monitoring of active processes in rocks and fluids allow for unprecedented data acquisition undisturbed by surface processes. A classic example is seismometer recordings in boreholes whose resolution and noise floor is improved by orders of magnitudes in comparison to surface measurements (Abercrombie 1997). Sealed long-term borehole observatories have been installed in many places on land and at sea that are designed to record changes in temperature, pressure, strain, tilt, acceleration, and hydrologic parameters, and to sample fluids or microbiology (e.g., Fischer et al. 2008; Kastner et al. 2006; Prevedel and Kück 2006; Araki et al. 2017).

Dynamics of Continental Crust

An unprecedented and still standing depth record in ultradeep scientific drilling was achieved in 1989 in the former Soviet Union when the Kola Superdeep Borehole reached 12,261 m

after 25 years of drilling (Kozlovsky 1987; Fuchs et al. 1990). Temperatures of less than 200 °C, low tectonic stress, and special lightweight aluminum tools were key to this success. The well intersected Paleoproterozoic to Archean meta-volcano-sedimentary sequences and plutonic rocks in the Kola Peninsula of the northeastern Baltic Shield. The main scientific targets were the origin and extent of ore deposits as well as the principal structure and composition of the deeper crust. Important findings include – beside the falsification of a hypothesized basaltic layer in an onion-skin-like deep crust – the discovery of high permeability and circulating fluids throughout the crust.

The German Continental Deep Drilling Program (KTB) aimed at principal physical and chemical processes and the geological evolution of the mid-European continental crust in an amalgamated collision zone (Emmermann and Lauterjung 1997). After 4 years of drilling of high-grade metamorphic rocks, a final depth of 9101 m was reached in 1994 at formation temperatures of ~270 °C. A Paleozoic suture zone cut by the borehole was found to be strongly deformed by post-orogenic Mesozoic fault zones in an antiformal stack. Down to 9 km, faults contain saline, gas-rich free Ca-Na-Cl-fluids, the geothermal gradient increases from about 21 to 28 °C/km, and fluids percolate freely along extensive fracture pathways. A detailed correlation of geophysical data with petrophysical properties at depth allowed for the calibration of surface geophysics to in situ conditions. Furthermore, for the first

Deep Scientific Drilling, Fig. 3 World map with important scientific deep drilling sites

time, the state of stress and the rheological behavior of an ultra deep crustal profile were analyzed in-situ. Determinations of the minimal and maximum horizontal principal stress between 3 and 9 km depth yielded a uniform stress direction except for a major fault at 7 km depth (Brudy et al. 1997). In conjunction with the deep main well, a 4000-m deep pilot hole just 200 m away allowed for the installation of a depth laboratory, for example, fluid level (Schulze et al. 2000) and induced seismicity experiments (Baisch et al. 2002).

Ultrahigh pressure metamorphic (UHPM) rocks form the 1000-km-long Qinling-Dabie-Sulu Belt in China, which was formed in a Triassic continental plate collision zone. From 2002 to 2005, a 5158-m deep core hole of the Chinese Continental Scientific Drilling project served to retrieve a vertical sample profile of the protracted multiphase deep (>150 km) subduction and rapid exhumation history of UHPM rocks (e.g., Liu et al. 2007; Zhang et al. 2006). The complex metamorphic path and its timing could be determined specifically in high-pressure minerals which survived late stage fluid-enhanced retrogression and overprint encased in zircons and other refractory accessories (Fig. 3).

Volcanic Systems

Volcanism is one of the most spectacular expressions of the dynamics of tectonic processes and the gigantic scale of

recycling working in the Earth. The scientific investigation of volcanic processes is also crucial for societal security and thus an important mission for science. Since most of the history of volcanism is encapsulated in rocks that are overlain by sediments, younger lava flows or beneath the sea, drilling is in many cases a critical tool for the investigation of the different types of magmatism reaching surface.

Mid-ocean Ridge Magmatism

As defined by Conference Participants (1972), ophiolites represent a suite of oceanic crust plus upper mantle. Beneath a sediment cover lava flows and pillow basalts overlay sheeted dike complexes, gabbroic rocks and, as part of the upper mantle, serpentinized peridotites and similar ultramafic rocks. Several holes drilled by the Deep Sea Drilling Program 1969–1985 and the Ocean Drilling Program 1985–1996 confirmed this structure but at the same time provided a much more complex picture. After several meters of lava flows were encountered in the early years of these programs, deeper parts of the oceanic plutonic rock succession were drilled in composite sections in tectonic windows and contributed much to the understanding of the ocean crust and mantle. Several drillholes in the Mid-Atlantic Ridge provided insight into slow-spreading modes with emplacement of ultramafic rocks. A 1508-m-deep hole (735B) penetrated a long section of gabbroic rocks of the slow-spreading Southwest Indian Ridge off Madagascar (Dick et al. 2000).

The first lava-dike transition was drilled in 6 Ma age crust of the Nazca Plate off Ecuador (Hole 504B) down to 2111 m below seafloor (Alt et al. 1996). And the first complete section of the upper oceanic crust was recovered by the Integrated Ocean Drilling Program at Site 1256 in 2005 and 2006 when the lava-sheeted dyke (1061 m) and the sheeted dyke-gabbro (1407 m depth) transitions of the Cocos Plate off Costa Rica were penetrated. The hole was deepened to 1521.6 m in 2011. The 15 Ma crust was formed in the East Pacific Rise by superfast spreading producing a thick succession (750 m) of lava flows, a relatively thin sheeted dyke complex and an upper gabbro section of still unknown extent (Alt et al. 2007). As the drilled fractionated gabbros (1407–1521.6 m) are not the residues of the overlying volcanics, the full sequence of plutonic ocean crust and the Moho transition to the upper mantle remains to be detected in future ocean drilling (Ildefonse et al. 2007; Teagle et al. 2011).

Active Volcano Drilling and Subduction-Induced Volcanism

The most common and typically most dangerous types of volcanoes on Earth are aligned along the subduction-related arc systems. They are typically fed by highly viscous andesitic to rhyolitic magmas whose degassing behavior is critical for their eruption mode, either effusive or explosive. While erosion and tectonics provide detailed insight into solidified and cooled volcanic structures, little is known about the physical and chemical conditions or permeability close to and in feeder fissures and magma conduits of active volcanoes. Despite challenging engineering and safety issues, some attempts have been made to drill into active volcanism. Still notable because of temperatures of above 1400 °C is the shallow drilling of the Kilauea Iki lava lake on Hawaii in the 1970s (Hardee et al. 1981). Furthermore, in Eastern California, the recent, rhyolitic Inyo Lava Domes were sampled to understand degassing mechanisms (Eichelberger et al. 1986).

A series of devastating eruptions with frequently occurring pyroclastic flows and vulcanian explosions in the early 1990s at Mount Unzen Volcano in southeastern Japan was accompanied by volcano-tectonic earthquakes and isolated tremor allowing for a geophysical pinpointing of the ascent path and surface appearance of magma. The identified conduit locale was within depth reachable by drilling, and justified drilling to sample in situ conditions after eruptions ended. Within the framework of the International Continental Scientific Drilling Program, the Unzen Volcano Drilling Project hit 2004 the conduit through an almost 2000 m long but 1500 m deep well (Sakuma et al. 2008). Deviated drilling steered by down-hole motors from the northern flank of Unzen was utilized to meet environmental and safety restrictions. Large-diameter casings were cemented in place to allow mud circulation for cooling of high-temperatures which were modeled to reach up to 600 °C. However, maximum temperatures were as low as

160 °C, and no gas kicks appeared due to enhanced permeability and 9 years of convection and groundwater circulation after the last eruptions. At 1996 m depth, rocks were cored that could be identified as feeder dyke material (Nakada et al. 2005).

In the next stage of scientific drilling into volcanic features, calderas will be explored because they form through collapse during super-eruptions – the most explosive volcanism on Earth. An outstanding example of an actively inflating caldera is the Campi Flegrei volcanic field in Naples, Italy (Troise et al. 2007). A shallow crustal magma chamber, strong geothermal activity with enormous release of volcanic gases, and recent episodes of unrest call for drilling as a tool to investigate the driving mechanisms. Similarly to the Unzen drilling, a deviated well is planned to be drilled from land under the Bay of Naples towards the center of seismic unrest in the heart of the structure at 3.5 km depth.

Mantle Plume Volcanism

Hot spots cut across lithospheric oceanic and continental plates and build up giant volcanic edifices in Large Igneous Provinces (LIP) and Ocean Island Volcanoes. Their build up requires vast melt extraction from the deep mantle and provides insight into mantle compositions, transport mechanisms, and the evolution of volcanic structures over space and time. Several boreholes of the Ocean Drilling Program opened windows into the Ontong-Java Plateau of the Western Pacific (Fitton et al. 2004) and the Kerguelen Plateau in the Southern Indian Ocean (Frey et al. 2000) to confirm their LIP origin.

In the Hawaii Scientific Drilling Project, the Mauna Kea volcano was cored with 95% recovery to a total depth of 3520 m (3508 m below sea level) to sample the evolution of plume melts over about 700,000 years as the volcanoes have drifted with the Pacific Plate over the Hawaii Plume (Stolper et al. 2009). The formation temperatures increase only from about 10 to 50 °C in the borehole (19 °C/km gradient below 2000 m) due to deep circulation of seawater in a complex hydrological regime including freshwater inflow as deep as 3000 m. The circa 850 m subaerial and 2440 m submarine layered lava and hyaloclastite accumulations represent almost 400 lithological units such as individual lava flows. They show geochemical and isotopic heterogeneity with tholeiitic versus alkaline magma transitions. This bimodal distribution of source components indicates a radial zoning within the melting region with a hot inner zone which does not contain entrained mantle material and must be based in the lowermost mantle region (Bryce et al. 2005).

A further drilling target are supercritical fluids at 4–5 km depth in the Iceland Deep Drilling Project (Fridleifsson and Elders 2007). Through coupled geothermal industry research and scientific investigation of in situ fluid-magma exchange, the first well at Krafla, Northern Iceland, hit rhyolitic magma

at about 2000 m depth before the well was cased for testing (Elders et al. 2011). The Yellowstone-Snake River HOTSPOT drilling project documented the volcanic history of this mantle plume through three boreholes (1821, 1912, and 1958 m deep) that cut through basaltic and rhyolitic series (Shervais et al. 2013).

Scientific drilling into volcanic rocks of the ocean crust provided the most important test and confirmation of the seafloor-spreading hypothesis. Samples retrieved from thickened ocean crust confirmed another type of seafloor volcanism forming Large Igneous Provinces which contribute large magma volumes to the continental crust as well. These LIPs seem to represent transient plume heads while the plume tails persist in Ocean Island Volcanoes. Hawaii served as pivotal example to drill deep into a single volcano to sample different parts of the plume and the volcanic history. Furthermore, recent penetrations into active volcanoes demonstrated the technical feasibility of such operations at very high temperatures. This access to deep volcanic processes is opening novel possibilities for monitoring.

Impact Craters

Almost 180 craters on Earth are currently known that have been formed by astrophysical chance when celestial bodies collided with Earth. The effects on life and the environmental consequences of the destructive forces as well as the input of extraterrestrial material, including organic compounds, is an overarching question in Earth systems history. Together with geophysical illumination, deep drilling into impact structures provides crucial data to study cratering, informing models of the impactors' size, impact angle, the resulting energy release through melting, evaporation, ejection, and, most importantly, provides data for charting the aftermaths of such dramatic events. The best studied example to date is the Chicxulub crater (Dressler et al. 2003) in which the approximately 10-km-large impactor penetrated the whole crust and caused upper mantle rebound and an exemplary drastic biotic turnover 65.5 Ma ago (Schulte et al. 2010). The impact ejected a spherule-rich ash layer all over the whole globe and released vast amounts of carbonate and sulfate gases previously bound in sedimentary rocks at the site of impact. The resulting darkness, cooling, geochemical cycle perturbations and sudden change of environment interrupted the food chain and led to the major extinction event at that time.

Since the year 2002, four main impact craters have been studied by scientific drilling: the 200-km-wide Cretaceous-Paleogene Chicxulub Crater in Mexico was drilled on land and offshore (Hecht et al. 2004; Gulick et al. 2019), the 1 Ma old and 12 km-wide Bosumtwi Crater in Ghana (Ferrière et al. 2008), the late Eocene, 60 km Chesapeake Bay Crater in the Eastern United States (Gohn et al. 2008), and the 14 km Lake

Elgygytgyn Crater in Chukotka, Siberia (Brigham-Grette and Melles 2009). One of the important results is an improved understanding of the cratering process. Giant km-sized megablocks of target rocks were drilled in the lower sections of the huge Chesapeake and Chicxulub craters at 800–1700 m depth. In Chicxulub, uplifted basement collapsed outward and formed a peak ring that was first covered in brecciated impact melt and coarse-grained suevite rocks followed by well-sorted suevites. Resurge deposits and reflected rim-wave tsunami layers sedimented atop within about a day. This impact rock layer is about 130 m thick and shows the extremely turbulent event sequence with, e.g., charcoal from impact induced wildfires in the tsunami layer (Gulick et al. 2019).

Active Fault Zones

Since the late 1990s, researchers have undertaken a wide range of ambitious projects aimed at drilling into active faults in a range of tectonic settings, both on land and at sea. These projects have been motivated by the recognition that fault zone process are poorly understood from surface data, and that a combination of (a) samples of fault materials from present-day active systems in the subsurface and (b) access through boreholes to *in situ* measurements and monitoring of ambient conditions in active faults, can provide key new observations for learning about these processes. Our understanding of the mechanics and dynamics of plate boundary faulting is severely limited by a lack of information on ambient conditions and mechanical properties of active faults at depth. A major goal in earthquake mechanics research is thus direct *in situ* sampling and instrumentation by drilling into the seismogenic zone of active faults, including both inter- and intraplate fault systems in many tectonic settings.

Understanding of the complex physics of tectonic faulting, earthquakes, and the generation of tsunami in the Earth's crust is one of the grand challenges of the geosciences in general and seismology in particular (Lay 2009). Because earthquakes take place deep below the Earth's surface, direct observation of processes acting in the faults themselves has generally not been possible; what we know about earthquake processes is derived from seismologic observations, geodetic deformation, and studies of exhumed rocks containing products of slip at depth long ago. Researchers have learned and inferred a great deal from these studies, but they are inherently limited. Much of fault zone drilling is aimed at understanding earthquake slip, but in fact fault physics encompasses a spectrum of slip and slip rates ranging from purely aseismic behavior, such as steady creep, through events such as slow earthquakes and episodic creep, to true seismicity. It is not yet clear how similar or distinct the physics of these modes of fault slip may be (Ide et al. 2007).

Hence, some of the key questions addressed through fault zone drilling projects include the following: What are the deformation mechanisms of fault slip in both aseismic and seismic conditions? Why is slip sometimes seismic, sometimes aseismic, and sometimes in an intermediate state, and what governs the transitions among these processes? How do earthquakes nucleate, and how does rupture grow and stop? Are there precursory phenomena in the fault or near field that indicate a preparatory phase to earthquake or slip nucleation? If so, can a prediction or early warning strategy based on borehole observation be developed? What are the processes governing tsunamigenic slip? What is the role of fluid content and fluid pressure in modulating faulting processes, especially during rapid seismic slip? How does permeability of the fault zone evolve interseismically and coseismically? What is the stress tensor in and around a fault zone throughout the earthquake cycle or other slip? What controls localization of slip vs. distributed strain in faulting?

Pursuing these questions, a number of major national and international efforts have been carried out or planned in recent years. These prominently include the San Andreas Fault Observatory at Depth (SAFOD), the Taiwan Chelungpu Fault Drilling Project (TCDP), and the Gulf of Corinth drilling on land, the Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE), the Japan Trench Fast Drilling Program (JFAST), and Hikurangi subduction drilling at sea.

Fault zone drilling projects are different in many respects from most other scientific drilling efforts. Rather than the complete stratigraphic intervals or sampling of broader rock volumes targeted by most other deep drilling, fault zone targets include *discontinuities* and small anomalous intervals. The targets of interest are often those locations of poorest drilling conditions, such as a highly fractured damage and gouge zone with potential for excess pore pressure above hydrostatic condition, anomalous stress state, weak rock, and other drilling hazards. The scientific approach commonly focuses on obtaining very extensive downhole measurements, logs, cores, and seismic structure in and around these fault zone environments. Measurements at the time of drilling as well as long-term observations are emphasized.

Nojima Fault Projects, Japan

Soon after the Kobe earthquake in 1995 (M6.9), several research teams drilled multiple boreholes into and across the shallow portion of the Nojima fault (the locus of that event) from ~750 m to ~1800 m depth (Ito et al. 1999). Detailed compositional and structural analyses identified a narrow fault core of gouge and surrounding damage zone, with asymmetric structure in the footwall and hanging wall (Boullier et al. 2001; Fujimoto et al. 2001; Ohtani et al. 2001; Tanaka et al. 2001). Shear wave splitting studies of aftershocks showed a rapid evolution of fast direction after the

earthquake, interpreted as evidence of fracture healing during a 12 monthly post-seismic period (Tadokoro and Ando 2002).

SAFOD, California

The San Andreas Fault Observatory at Depth borehole was drilled from 2004 through 2007 into the San Andreas fault in central California at the northern end of the locked Parkfield segment and the creeping section of the fault zone (Williams et al. 2010). A vertical pilot hole was drilled in 2002 to circa 2 km depth (Hickman et al. 2004), and the main hole was later drilled in several phases in a “dogleg” deviated 55° across the steeply dipping San Andreas fault zone to a vertical depth of 2.6 km (Fig. 4; Hickman et al. 2007). The initial main borehole was logged and cased; repeated casing diameter logs over time showed that two intervals of casing several meters wide were actively deforming, interpreted as a manifestation of creep in two discrete fault zones (Hickman et al. 2007). In 2007, the hole was reentered and sidetracks were drilled to obtain core samples (Williams et al. 2010). A core interval of approximately 40 m was obtained from one of the two identified major fault zones and additional cores were collected from adjacent wall rock intervals. Borehole seismometers installed at SAFOD detected earthquakes as small as M2 within a few hundred meters of the source, allowing unprecedented high-frequency detection of source processes (Ellsworth et al. 2007). A notable result from SAFOD has been the absence of evidence for either a thermal anomaly from frictional heating around the fault core or an excess pore fluid pressure substantially above hydrostatic anywhere in or around the faults, as well as geochemical evidence that the fault zone is a permeability barrier to cross-fault flow (Hickman et al. 2007; Wiersberg and Erzinger 2007), simultaneously adding evidence for absolute fault weakness in the San Andreas and opening new questions about the source of that weakness.

Taiwan Chelungpu Drilling Project, Taiwan

The devastating 1999 M7.6 Chi-Chi earthquake in Taiwan was a thrust event in a collisional tectonic setting that exhibited very large slip (>10 m), including large surface displacements, on the Chelungpu fault. The principal objective of drilling was to sample the main slip surface or zone, if one could be identified, at a relatively short post-seismic interval. The fault zone was drilled in 2004 and 2005 in an area of high-velocity large slip during the main shock, and crossed the fault zone and several hundred meters of the footwall in two adjacent holes (Ma et al. 2006). The main slip zone and several subsidiary (or older) fault cores were identified in the borehole at ~1100 m depth (Hung et al. 2007). Studies of the fault gouge particle size, thickness, and composition have yielded quantitative estimates for the work done in forming gouge and damage (fracture energy), contributing to the understanding of energy budgets during earthquakes (Ma et al. 2006).

Deep Scientific Drilling,

Fig. 4 Sketch of drilling design in the San Andreas zone observatory at depth

Wenchuan Earthquake Fault Scientific Drilling Project (WFSD), Sichuan, China

The devastating Wenchuan earthquake (M7.9) of May 12, 2008, caused at least 68,000 deaths. It occurred on a reverse fault in crystalline basement rocks, and slip propagated to the near surface. Only 178 days after the earthquake, the Wenchuan Fault drilling program was begun in order to access the co-seismic slip zone for sampling and in situ observations, in six boreholes along the Longmenshan Fault system. The boreholes elucidated a complex structure of the fault system, thermal pressurization as fault-weakening mechanism, an extremely low frictional coefficient for faulting coincident with graphite occurrence and a relationship between deep fluid appearances and seismicity (Xu and Li 2019).

Geophysical Observatory in the Eastern Sea of Marmara, GONAF

A prime example of earthquake-endangered megacities is Istanbul, Turkey, due to its close proximity to the extremely active North Anatolian Fault Zone that routes compartmentalized just a few kilometers south of the city center through the Marmara Sea. In contrast to the majority of other fault zone drilling projects the GONAF boreholes did not penetrate the fault itself but were utilized to deploy extremely sensitive

borehole seismometers and strainmeters down to 300 m together with surface stations as a permanent observatory of deformation around the Sea of Marmara (Bohnhoff et al. 2017). The acquired high-resolution data from depth have meanwhile been used to elucidate the coeval release of slow strain and enhanced local seismic moment (Martinez-Garzon et al. 2019). These accomplishments are leading to an ongoing expansion of the GONAF and related networks for monitoring of the whole Marmara region and beyond.

Deep Scientific Drilling to Study Reservoir-Triggered Earthquakes in Koyna, India

A key societal challenge in Earth science remains predicting earthquakes. There is an earthquake-prone zone in Western India where such forecasts are possible as artificial water reservoir-triggered earthquakes occur repeatedly after monsoon rains since 1962. While the region is seismically stable, rooted in Precambrian basement overlain by about 1200 m of Deccan Trap basalt flows, a secluded zone of recurrent seismicity stretches North-South of two man-made water reservoirs. Periodic earthquakes at depths between 2 and 7 km offer a unique opportunity to install an observatory to monitor mechanical and physicochemical properties of rocks and fluids in the near-field of these events (Gupta and Nayak 2011).

The 3-km-deep pilot well KFD1 drilled in 2017 transects 1247 m of basalt and 1767 m of granitic-gneissic basement rocks to shed light on deformation processes. Borehole geophysical logs analysis revealed anomalous zones with stress-induced shear wave anisotropy indicating the orientation of maximum horizontal compressive stress related to the active subsurface fault damage zone (Goswami et al. 2019, 2020). For the next phase, it is planned to drill a main well towards the proper fault zone down to about 6 km depth to install a borehole laboratory at depth for direct and permanent monitoring of an intraplate seismic zone.

Subduction Zone Fault Drilling at Sea

For well over 30 years, drilling efforts have targeted active large offset thrusts and decollement faults in subduction zone settings, but these have mostly been in areas shallower than the depth of seismogenic strain accumulation and release. Beginning in the 1980s with the Barbados Accretionary Wedge at the Atlantic Caribbean plate boundary, drilling was aimed at understanding the faulting conditions, ambient pore fluid pressure, and mechanics in a very low angle (~2 degree dip) décollement thrust fault at the base of an accretionary wedge (Moore 1989). Drilling, downhole logging, and long-term borehole observatory measurements there demonstrated that the fault zone was a mechanically very weak interval with high permeability, high excess pore fluid pressure, and patchily distributed areas of anomalously high porosity (Moore et al. 1998; Fisher 2005). Drilling at Costa Rica off the Nicoya peninsula also elucidated the structure of a shallow decollement zone. Structural studies and geochemical tracers of hydrological flow paths suggest that two strongly decoupled systems exist above and below the ~20-m-thick main fault zone, which acts simultaneously as a low-permeability barrier to cross fault flow and a high-permeability channel for along-fault flow (Tobin et al. 2001). Installation of a sealed borehole monitoring system there documented an apparently weakly overpressured décollement zone that exhibits temporal pressure excursions tied to apparent aseismic transients recorded geodetically on land (Davis and Villinger 2006). Similarly, instrumented boreholes at the Nankai Trough off Shikoku Island in Japan show pressure transients associated temporally and spatially with swarms of very low frequency earthquakes, suggesting a long-distance (tens of km) poroelastic connection between the earthquake events and the boreholes (Davis et al. 2006). The same data exhibit long-term pressure trends interpreted as a response to gradual interseismic strain accumulation.

Drilling to understand megathrust earthquake processes and fault zone properties has been a major focus of both the Integrated Ocean Drilling Program and the International Ocean Discovery Program (IODP), and was a primary justification for the construction of the riser drilling vessel *Chikyu*. Major fault drilling programs have been undertaken by IODP

at the Nankai Trough, Sumatra, Japan Trench, Costa Rica, and Hikurangi (New Zealand) subduction zones. The spate of extremely large earthquakes that began with the Sumatra 2004 M9.2 and continued with the 2010 Maule M8.8, the Tohoku 2011 M9.1, and others has led to renewed urgency to investigate these events. Scientific ocean drilling has contributed to a new view of how fault locking, slip, and friction work. IODP Expedition 362 drilling at Sumatra showed that diagenesis of well-cemented sediments led to unexpected conditions of frictional instability to the trench for the 2004 event (Hüpers et al. 2017), facilitating large slip. Nankai drilling on Expedition 316 in 2007 revealed evidence of frictional heating of fault zone rocks during past slip, indicative of rupture reaching shallower levels of the megathrust than was thought possible theretofore (Sakaguchi et al. 2011).

Beginning in 2007, IODP embarked on its most ambitious fault zone drilling project to date, to drill a transect of boreholes at the Nankai Trough, including one ultradeep site targeting the plate boundary fault at 5 km below the sea floor. The Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE) project represents the first attempt to drill, sample, and instrument the seismogenic portion of a plate-boundary fault or megathrust within a subduction zone, where the 1944 M8.1 Tonankai earthquake slip zone is located, and where more recently discovered very low frequency earthquakes, seismic tremor, and transient slow slip have all been detected (e.g., Sugioka et al. 2012). The fundamental goal of NanTroSEIZE science plan (Tobin and Kinoshita 2006) has been to access, sample, and then instrument the faults in aseismic and seismogenic regions of the megathrust system. Over the period from 2007 through 2019, 12 *Chikyu* expeditions have targeted this zone, reaching a maximum depth of 3262 m below the sea floor, a record in scientific ocean drilling. Key results have included the delineation of the fault zones, and the establishment of the first three real-time cabled borehole observatories in a subduction zone system which have detected many transient slip events (Araki et al. 2017; Tobin et al. 2019). The long-range objective of drilling into and instrumenting the plate interface fault zone at 5–7 km depth remains as a future objective.

Japan Trench Fast Drilling Project (JFAST)

The unprecedented discovery of very large (40–80 m) fault slip to the trench region during the 2011 Tohoku M9.1 earthquake and tsunami led to “rapid-response” drilling being planned and executed within 13 months of the earthquake. JFAST was carried out as IODP Expeditions 343 and 343 T (Chester et al. 2013). The primary objective was to identify and sample the fault zone that slipped near its upper end at the trench, and measure the residual thermal anomaly from the frictional heating of fault slip. A challenging aspect of the drilling was the extreme water depth of nearly 7000 m at the sea floor. A borehole of 844 m was drilled, the slipped fault

material recovered, and its frictional properties documented (Ujiie et al. 2013). Subsequently, a thermistor string was sealed into the borehole for several months, and detected the frictional heat signature of the earthquake, measured as 0.3 °C above the background. From these data, Fulton et al. (2013) concluded that slip had occurred under extremely low effective friction, with a coefficient of only 0.08. These are the first data to quantify fault slip conditions for large earthquakes.

Unconventional Resources: Geoenergy

Among the unexplored geological resources requiring drilling for basic scientific research are gas hydrates, in which methane and other gaseous hydrocarbons combine with water to form crystalline, ice-like structures (clathrates). Two widespread environments of their occurrence have been known for a long time: in sediments of the continental slopes where they simulate bottom reflectors in seismic images, and below permafrost in polar regions (Kvenvolden 1988).

Little is known about the global abundance and distribution of gas hydrates, and even less about the physical and chemical parameters that affect the formation and stability of gas hydrates. They bear a high potential of generating continental slope instabilities causing giant submarine landslides and contributing significantly to the atmospheric greenhouse effect when released into atmosphere (Dickens 2003). At sea, the best studied, drilled areas are in the Eastern Pacific off Vancouver Island and at Blake Ridge in the western Atlantic Ocean off Georgia (Tréhu et al. 2006). Continental gas hydrate accumulations were drilled in the Mackenzie River delta in northern Canada (Dallimore and Collett 2005). Two observation wells and one central production well drilled to 1200 m depth were used for an extensive field program including coring, downhole logging, cross-hole experiments, and production testing. All three wells show massive thermogenic methane gas hydrate accumulations between 890 and 1100 m depth with the highest concentration at the base of the gas hydrate stability zone (Takahashi et al. 2005). Similarly, in marine sediments, the hydrates are concentrated in coarse-grained, high-permeability layers.

The Iceland Deep Drilling Project, IDDP

Global decarbonization plans require enhanced regenerative energy production. Accordingly one of the emerging research objectives in Earth science is geothermal energy. Much effort is invested in identifying (and tapping) hot water and steam and heat exchangers at depth or creating such systems artificially. Although such system can be tapped for up to some tens of years, the utilization of high enthalpy supercritical

magmatic fluids or the exploitation of magmatic heat and accompanying crystallization energy promises ten times higher energy output. In an attempt to test the theory of supercritical fluids (22 MPa and 374 °C for pure water) utilization, the IDDP project drilled in 2009 at Krafla in Iceland, a well in basaltic rocks that was intruded at 2100 m depth by rhyolitic magma (Elders et al. 2011). Drilling was stopped due to challenging 900 °C conditions but the well was tested for directly utilizing magmatic heat and inspired planning for a magma test site (Eichelberger 2019).

The second IDDP well drilled on the Reykjanes Peninsula in SW Iceland to about 4500 m depth reaching about 535 °C undisturbed formation temperature (436 °C measured borehole temperature) and 34 MPa fluid pressure. The drill cores retrieved from different depths confirm increasing hydrothermal alteration of basaltic dike rocks up to pyroxene hornfels facies (Fridleifsson et al. 2018). Although cold-water injection was seismically monitored and fluid inflow zones could be characterized, a test confirming energy gain from supercritical magmatic fluids remains pending.

Summary

This chapter summarizes the most significant, but not all, deep scientific drilling projects that have been carried out in recent years by international research teams. Key goals of these projects encompass topics of high societal relevance such as a better understanding of the physics driving geological disasters and a wise utilization of resources. Various several kilometer deep drilling ventures allowed for unprecedented sampling and in situ monitoring of dynamic processes governing formation and restructuring of the Earth's crust such as collision events, volcanism, faulting, or impact cratering. Despite grand engineering challenges, deep Earth access techniques are now available for novel burgeoning scientific exploration. Scientific drilling promises to be an integral tool of research generating new observations for the time to come.

Definition

Deep Seismic Reflection and Refraction Profiling

Classically, multichannel recording, along a measurement line, of (mostly) seismic P-waves, artificially generated using large energy sources, after these have traveled deep thru the earth's crust (and upper mantle). Later developments include multicomponent recording enabling analysis of shear waves. Deep reflection profiling is mostly done using vibrators (on land) or air guns (in water) at near-vertical distances (8–12 km) to image the structure of the crust and upper mantle. Wide-angle reflection/refraction profiling uses large explosions and recording distances (200–300 km), primarily to obtain velocity information down to the upper mantle.

Notational Notes

Below, all capitals (e.g., DSRRP) will be used for acronyms and italicized phrases within double quotes (e.g., “*Seismic Noise*”) will refer to articles elsewhere in *this* volume.

Introduction

Vibrations caused by earthquakes are known to travel great distances and provide valuable information about the internal structure of the earth. Explosions and other artificial sources could also be used to generate such waves. Man-made

earthquake signals have several advantages of their own, e.g., their location – both in space and time – is precisely known. Further, due to relatively shorter distances of observation, higher frequencies are better preserved and allow a better resolution of the subsurface structure. Development of *marine seismics* has extended the coverage of this technique to offshore regions too.

As a science, *deep seismics* is positioned between exploration seismics and seismological studies. With the shared theory of wave propagation in (visco)elastic media, similar instrumentation, and computer-intensive processing/interpretation techniques, there is increasing *overlap* between these two approaches. Improvements in data acquisition and processing have extended the depth range of exploration seismics from basin level downwards and now cover the entire continental crust down to *Moho* and the upper mantle region immediately below it (50–100 km). Such studies are called deep seismic sounding, long-range reflection-refraction, wide-angle crustal-seismics, etc. depending upon their focus. The acronym *DSRRP*, derived from the title, will denote studies using seismics to study the (continental) crust, including active and passive continental margins, and the upper mantle of the earth, using man-made and natural sources.

There are several good resources about the general theory of wave propagation in elastic media (e.g., Aki and Richards 2002) and exploration seismics (e.g., Sheriff and Geldart 1995 and ► “Seismic Data Acquisition and Processing”); special topics pertaining to the latter in the context of DSRRP will be elaborated whenever needed.

Basic Principles

Figure 1 illustrates the principle of the seismic experiment using a simplified earth model. Here, a horizontal boundary separates the top layer of velocity (actually wave speed) v_1 and thickness d from a half-space of velocity v_2 , with $v_1 < v_2$, mostly valid within the earth. Wave energy, generated at the source, travels through the media and is recorded by many (usually hundreds of) receivers on the surface as *seismic traces*, their collection being a *seismic record*. Plot of a record – amplitudes as a function of recording distance versus travel time – shows distinct spatiotemporal *alignments*, representing different wave types (*phases*), three of which are sketched in the figure. Depending upon their travel path, the phases show up in the record as *first* or later arrivals and carry information about some properties of the medium. The amplitudes of these phases – and their variation with the recording distance (*offset*) – yield additional information about material properties of the medium, e.g., *density*, *elasticity*, etc.

The subject matter of this article forms an extension of exploration seismics. Sheriff and Geldart (1995) and Liner

(2004) provide good coverage of its various aspects, e.g., theory and data acquisition, processing, and interpretation. More detailed treatment of these topics is provided by Aki and Richards (2002; theory of wave propagation), Vermeer (2002; data acquisition), and Yilmaz (2001; data processing). DSRRP-specific modifications/extensions to the standard field and processing procedures will be described later. Based on Fig. 1, a brief overview of some key concepts from *seismics* – relevant to DSRRP – follows.

Linear arrivals represent the travel times of both *direct* and *refracted* arrivals, if v_1 and v_2 are constant, the slopes (dt/dx) being inversely proportional to the corresponding velocities. Using these, and the *intercept time* (t_{int} , Fig. 1) of the refracted arrival, the layer thickness d can be calculated.

Critical distance is the minimum recording distance for observing the refracted wave. According to Snell’s law, only when the energy is incident on the boundary at the critical angle ($= \sin^{-1} \frac{v_1}{v_2}$) will it be refracted *along* the boundary, will propagate with the velocity v_2 of the lower medium, and will keep sending energy back into the upper medium according to Huygens’ principle.

Crossover distance denotes the distance, beyond which the faster refracted phase overtakes the direct wave ($v_2 > v_1$) and becomes the first arrival; the latter can also be used to determine the thickness d . In a layered earth with velocities increasing with depth, refraction arrivals from deeper boundaries become the first arrival after their respective crossover distances. *Historical note:* A. Mohorovicic used the overtaking of the direct P-phase from an earthquake by a faster (refracted) one, which he called P_n , to infer the thickness of the earth’s crust and the presence of a higher-velocity medium underneath (IGCP-559 2010a); the boundary defining the base of the crust has since been named *MOHO* in his honor.

Reflections represent that part of wave energy incident upon a layer boundary, say at the point “V” in Fig. 1, which will be transmitted back into the upper medium, according to Snell’s law. The *reflected* arrival is hyperbolic in shape, with its apex at time t_0 , corresponding to the vertical two-way time ($= 2d/v_1$) from the source down to the boundary and back. Reflection amplitude is sensitive to the (contrast of) material properties across the boundary and the incidence angle and provides valuable additional information regarding the media.

Supercritical incidence occurs, as the recording distance increases, with the incidence angle changing in Fig. 1 from (near) vertical (e.g., point “V”) through the critical incidence (e.g., point “C”) to supercritical (e.g., point “W”). Note that the reflection hyperbola becomes asymptotic to the linear arrival belonging to the layer above but never crosses it. This relationship also holds in a multilayered situation with increasing velocities.

Wide-angle incidence implying large recording distances (compared to the target depth) sees a sharp increase of

Deep Seismic Reflection and Refraction Profiling, Fig. 1 Schematics of a multichannel seismic experiment to image the earth (layer of wave speed V_1 overlying a half-space of wave speed V_2). Energy travels from the source through the medium and is recorded by the receivers (filled triangles), planted in the ground, as *seismic traces*. Dash-dots represent energy *directly* traveling from source to the

reflection coefficient and enables imaging of crustal boundaries with small contrasts. The quantity $t_x - t_0$ (Fig. 1), called normal moveout (NMO), can be measured well in this region and helps velocity estimation. The seismic signal window gets compressed though at large offsets due to the geometry (kinematics) of the travel time curves (Fig. 1, top).

Modern DSRRP represents an integration of the *near-vertical* and *wide-angle* modes of seismic investigation. While near-vertical multichannel reflection seismic (NMRS) provides powerful tools for structural imaging developed for the exploration industry, wide-angle reflection-refraction (WARR) is valuable for constraining the velocities of the crustal units and thus provides the geological framework.

Data Acquisition

Seismic field measurements need three components, viz., man-made *source* to produce seismic energy (usually at the earth surface or within water), which then propagates within the earth, *receivers* (usually also at the surface) to pick up a part of this energy returning back after reflection/refraction/diffraction (scattering in general) from within, and *recorder* to store the received signals (nowadays after digitization); see ► “[Seismic Data Acquisition and Processing](#)” for details.

Sources used in DSRRP have to be stronger than those in exploration, as the distances traveled by the seismic

receivers along the surface, continuous lines show *reflections* from the layer boundary, and dashes indicate energy *critically refracted* along the boundary. The upper half uses the same patterns to show the *travel times* of these three phases. Letters *V*, *C*, and *W* indicate points representing (near) vertical, critical, and wide-angle incidence of energy on the boundary

waves – both vertically and especially horizontally – are much larger. Such sources including quarry blasts using several kilotons of TNT – sometimes under water – were recorded over long distances, often across international boundaries (Steinhart and Meyer 1961; György 1972; Kaila et al. 1978). Calibrating and monitoring of nuclear explosions necessitated several long-distance (mostly) refraction profiles, with nuclear explosions as sources (see ► “[Traveltime Tomography Using Controlled-Source Seismic Data](#)”). Later, very long-range crustal seismic measurements were carried out in the Soviet Union using dedicated *peaceful nuclear explosions* (Pavlenkova and Pavlenkova 2006). Although chemical explosions continue to be used for WARR studies, powerful hydraulically driven mechanical vibrators on land and large compressed air sources (air guns) under water are preferred nowadays for NMRS; these have sufficient energy to return signals back to the surface from Moho and upper mantle.

Receivers used in DSRRP are similar to those used in seismology and in exploration seismics but need some special characteristics. Long measurement profiles imply deployments over a large distance/area, often necessitating stand-alone capabilities, especially for power supply and storage capacity; see Mereu and Kovach (1970), in which mention is also made of an early German effort (MARS-66) using a portable four-channel analog tape recorder. Modern DSRRP receivers digitize in real time and can often be

programmed to record at certain pre-arranged time windows (see [Texan](#) in the references). For near-vertical land/marine deployments, standard industry equipment is used; these are frequently cable-free and use radio communication for data transfer.

Time-of-shot recording was the weakest link in DSRRP – especially for WARR deployment, covering distances of several hundred kilometers. Early experiments used short-wave radio link or the parallel recording of a continually broadcasting radio transmitter. Availability of GPS-based time signals and high-quality internal clocks has mitigated this problem.

Field Layouts

Receiver arrays were utilized early on for long-range refraction-seismic studies for their directivity vis-a-vis possible nuclear test sites – some becoming permanent installations, e.g., NORSAR (Norway), GBA (India), and WKA (Australia). Recently, the Program for Array Seismic Studies of the Continental Lithosphere (see [PASSCAL](#) in the references) has made hundreds of identical instruments available, enabling temporary deployment in several countries. Using these, with fixed and portable deployments recording both active and passive sources, a 15-year observation has been completed in the USA. See Fig. 2 and [USARRAY](#) and [EarthScope](#) in the references.

Multichannel near-vertical land/marine studies use standard industry equipment and deployments (see also ► “[Seismic Data Acquisition and Processing](#)”), the main difference being a much longer recording time (15–30 s or longer). When using vibratory sources on land, long sweep and listening times are needed too. If the continental crust is covered by a shallow water layer (e.g., British Isles), marine data acquisition offers twin advantages of speed and better signal-to-noise ratio, enabling better imaging.

DSS-DSRRP onshore-offshore recorded earlier from near-vertical outward till at least the p_n -phase (refraction below Moho) was recorded as the first arrival (Gamburtsev 1952). Outside the Soviet Union, this technique was first extensively used in India starting 1972, to study the tectonic framework of the subcontinent (Reddy et al. 1999) and was later adapted for sub-basalt (*Deccan Trap*) exploration. Many DSRRP investigations nowadays combine the two modes – an industry standard *common midpoint* profile (NMRS) is frequently interspersed with a few widely spaced explosions, observed at large distances (WARR). Variations include two-ship marine recording and simultaneous onshore-offshore measurements, useful for investigating continental/accretionary margins.

Special Processing and Interpretation Tools

Processing of DSRRP data followed initially the standard industry scheme. Soon, however, the special needs of deep seismic data were realized. Consequently, schemes using modules newly developed by the industry/academia were established, and older data were frequently reprocessed, often resulting in *improved* images and interpretation (Cook and Vasudevan 2006).

Line drawings were used initially to prepare DSRRP data for migration and interpretation. NMRS signals are generally weak and laterally discontinuous and embedded in a noisy background. Lines were therefore drawn on the paper section to form more or less continuous alignments – taken to represent boundaries for interpretation. The process was strongly subjective. This approach paralleled interpreting WARR data with long refraction segments, which neglected signals with limited lateral continuity.

Coherency filter was proposed to mitigate this. Kong et al. (1985) formulated a procedure to *automatically* identify *signals* present in the seismic section. Using the concept of *phase coherency*, it uses a few user-defined parameters, to yield *repeatable* results, and can detect *weak but laterally continuous* signals in the presence of incoherent noise – although it does not preserve (relative) amplitudes. Some form of coherency filtering is nowadays commonly used for processing NMRS data.

Noise reduction versus amplitude preservation is, however, an important issue because modern processing techniques can use amplitude information to advantage. An example of amplitude-preserving noise reduction is provided by Kumar et al. (2011), wherein curvelets are used to suppress incoherent seismic noise.

Statistical processing of DSRRP data, for objective high-grading using a coherency criterion, was proposed by Hansen et al. (1988), based upon statistical hypothesis testing. It provided some estimate of the robustness of the results, albeit at the cost of additional computation time. Vasudevan and Cook (1998) introduced the concept of *skeletonization* to delineate regions of the deep crust based upon their seismic signature; van der Baan (2000) included local signal statistics for high grading the signals.

Attempts have also been made to treat the entire deep-reflection wave field as backscattering from a random medium (Hurich 1996; Hurich and Kocurko 2000; Pullammanappallil et al. 1997) and analyze it to extract parameters describing the medium (see below).

Vertical vis-a-vis horizontal tectonics used preferentially could lead to different interpretations of the same data. DSS profiles in György (1972) and later literature (e.g., Kaila et al. 1979) frequently contain intra-crustal normal faults. With

Deep Seismic Reflection and Refraction Profiling,

Fig. 2 Plot of EarthScope stations – permanent and temporary – including those of USARRAY. For details, see legend in the inset. Full resolution original at <http://www.earthscope.org> → Research → Maps → EarthScope Overall Maps (Archive) → June 2015. (Figure courtesy of www.earthscope.org)

EarthScope Stations Status as of June 2015

the paradigm shift associated with the formulation of plate tectonics, some of these may need to be revisited. Gibbs (1986) illustrated this by using a DSS section sans the earlier interpretive lines for an alternate interpretation.

Main Results

NMRS recordings from 12 to 15 s contain coherent reflected energy from down to 35–45 km, depending upon the presence/absence of sedimentary cover. Crystalline crust appears to be much more reflective than assumed earlier, although there are transparent zones too. In general, the mature continental middle crust is less reflective than the lower crust – probably indicating differences in their rheology (brittle vs. ductile). Intra-crustal dipping reflective zones – of both thrust and normal fault types – are encountered frequently. At times, these cut through the Moho into the upper mantle as *frozen* evidence of paleo-subduction. Moho appears frequently as the termination of *diffuse* reflectivity, the boundary itself occasionally showing sharp displacement (sign of strength).

WARR recordings can be modeled with longer boundaries separating tectonic/velocity blocks at a regional scale. These also provide occasional evidence of *sharp* offsets in crustal boundaries including Moho; the latter seems, in some cases, to be *doubled*.

The role of deeper structures – especially *deep faults* – in controlling the evolution of shallower geology, e.g., deposition, deformation, fluid movement, etc., is being increasingly appreciated. The knowledge gained is of economic significance – for understanding *systems* associated with economic accumulation of hydrocarbons and minerals and to help steer search for them.

Early DSS(RP) in Eastern Europe has been nicely summarized in György (1972), from which Fig. 3 is taken.

It shows a part of a long-offset (≈ 233 km) DSS profile recorded in Ukraine in the 1960s, as part of extensive DSS surveys in Eastern Europe, which had established the observability of deep refracted and reflected phases in the wide-angle range. High apparent velocity of the refracted P_n -phase (first arrival at large offsets) and its relationship with (later) reflected phase help identify the base of the crust as their origin. Some figures in the above reference also show near-vertical reflections from the Moho.

György (1972, pp. 44–68) includes on page 66 a contour map of the Moho depth below Ukraine, the detail of which, although debatable, is impressive, especially considering its vintage. It is based on an astounding 6000 line km of DSS profiling with a dense network, following the methodology described in Gamburtsev (1952). The contours indicate depths between 22.5 and 55 km, with rapid lateral variations at places. The latter were interpreted as *deep faults* displacing the Moho.

(Inter)national consortia in DSRRP started in 1975, when an industry crew measured a reflection profile in Texas, using a vibratory source, with a recording time of 15 s (Finlayson 2010b). A large amount of data has since then been collected/analyzed in several national academic industrial collaborations – Table 1 provides a partial overview; see also IGCP-559 (2010c) for more details.

Recently, some international DSRRP experiments have studied specific geological problems, e.g., Himalaya and Tibetan Plateau (Zhao et al. 1993), active continental margin in Central Andes (ANCORP Working Group 2003), and structures in East Antarctica from SEAL geotranssect (Kanao et al. 2011). Such transects are often multidisciplinary in character, e.g., Palomeras et al. (2011).

International biennial symposia have been organized (roughly) every 2 years since 1984 to showcase the data and discuss the results from DSRRP surveys. The publications resulting from these meetings provide a historical record of

Deep Seismic Reflection and Refraction Profiling,

Fig. 3 DSRRP data recorded in Ukraine in the 1960s. Both refracted and reflected energy is clearly visible at a distance of about 233 km and is correlatable trace to trace with a geophone spacing of 100 m. The first arrival, here marked P^M , is the head wave from Moho (P_n), and the strong later phase, marked P^M_{refl} , is the wide-angle reflection from the base of the crust. (Figure courtesy of *Geophysical Transactions* from György (1972, p. 50))

the progress of DSRRP – with respect to both technological advancement and scientific knowledge: Barazangi and Brown (1986a, b), Matthews and Smith (1987), Leven et al. (1990), Meissner et al. (1991), Clowes and Green (1994), White et al. (1996), Klemperer and Mooney (1998a, b), Carbonell et al. (2000), Thybo (2002), Davey and Jones (2004), Snyder et al. (2006), Heikkinen et al. (2011), Rawlinson and Goleby (2012), Santosh et al. (2014), Carbonell et al. (2016), Rawlinson et al. (2017), and Malinowski et al. (2019). Some additional information is also available in IGCP-559 (2010b).

(Re)processing, synthesis, and interpretation of the vast amount of DSRRP data – near-vertical and wide-angle – are not easy. The data quality depends upon the geological settings and the data acquisition technique and parameters used. Uniform processing of this dataset of mixed quality/vintage is necessary though for regional syntheses and interpretation, to understand the internal architecture of the continental crust (e.g., Phinney and Roy Chowdhury 1989; Cook and Vasudevan 2006).

Results from DSRRP contain several surprising features – some of which are still being interpreted – and have yielded new insights into the processes that shape the continental crust. Below are some of these highlights; the acronyms referring to the consortia/projects are explained in Table 1.

Imaging deeper with multichannel exploration seismics began in 1975. The COCORP consortium – the acronym is reported to have been coined past midnight at a bar in Mexico – pioneered the use of industry standard sources (vibrators), recording layout (NMRS), and processing for deep seismic profiling on land and obtained useful signals from depths of 40–50 km, by using 4–5 vibrators simultaneously and extending the recording time (Oliver et al. 1976). Later, similar studies confirmed that the crust underlying the basement possesses variable reflectivity, including some *transparent* regions. Moho, the base of the crust, often showed up on such images as the termination of a zone of diffuse reflectivity, and not as a long and sharp boundary inferred from earlier (refraction) studies.

One of the early surprises of the COCORP lines was the discovery of a mid-crustal zone of strong reflectivity below southern Georgia, USA; the *surrency bright spot* was reconfirmed during a later survey (Pratt et al. 1993). Such zones have since been reported in other surveys too, e.g., the *Quebrada Blanca Bright Spot* (QBBS) in Andean subduction zone (ANCORP Working Group 2003) and below the Dnieper-Donets paleorift (Pylypenko et al. 2011). The possible causes of this strong reflectivity remain controversial (see below).

Besides WARR recordings of quarry blasts, Germany had an early start in near-vertical recordings of deep reflections and statistical evaluation of their amplitudes (e.g., Dohr 1957; Dohr and Fuchs 1967). More recently, their DEKORP program has included investigations across active collisional

Deep Seismic Reflection and Refraction Profiling, Table 1 Some (inter)national DSRRP efforts

Acronym	Location	Period	Remarks
COCORP	USA	1975 onwards	Pioneered near-vertical imaging

zones, e.g., Alps (Gebrande et al. 2006) and the Andes (ANCORP Working Group 2003). For details, see DEKORP in the references.

Marine seismic imaging of the continental crust was seized upon to (partly) alleviate the unfavorable *signal-to-noise ratio* (SNR) for deep seismic data acquisition on land, e.g., noise from traffic, industry, etc. – although marine seismics has its noise sources too. Phinney (1986) used data from a 48-channel marine survey (recorded by USGS during 1973–1979) over the Long Island Platform. The original stack sections of lines 36 and 23, reprocessed to 12 s, showed clear evidence of a rich crustal architecture, with half grabens, wedges, and other tectonic features indicating both compressional and extensional phases of a Wilson cycle.

Existence of known – and expected – hydrocarbon-bearing structures had attracted marine seismic exploration activity in the 1970s and 1980s to the waters around the British Isles. The latter, surrounded by North Sea and the northeast margin of the Atlantic Ocean, are a part of the European continental shelf. Starting 1981, this situation was utilized to great advantage by the BIRPS consortium – essentially by extending the marine seismic exploration recording time to 15 s. The

very first profile, MOIST (recorded by the preceding BURPS group), contained strong reflections from the lower crust, Moho, and upper mantle (see Fig. 4), which could be connected to surface geology on land (Smythe et al. 1982), and even prompted correlation of tectonic evolution across the Atlantic (Brewer and Smythe 1984).

Later BIRPS profiles, e.g., WINCH (Brewer et al. 1983), provided evidence for shallower/younger tectonics being controlled by older/deeper crustal structures. The DRUM profile extended the recording to 30 s. The density of coverage and the quality of data allowed Flack and Warner (1990) to map deep reflections in 3D and enabled Chadwick and Pharaoh (1998, p. 268) to produce a contour map of Moho beneath the UK, which may be compared with a similar map below Ukraine (György 1972, p. 66) mentioned earlier.

Integrated transects, using additional geophysical tools, e.g., magnetotellurics, electromagnetics, and geochronology, characterized the LITHOPROBE program in Canada. It took advantage of the geology to investigate both ancient processes, e.g., assembly of continents and modern crustal dynamics of active subduction, detachment, and imbrication. For example, the Kapuskasing Uplift, one of the few lower crustal exposures on earth surface, was imaged in the KSZ transect (Percival et al. 1989), whereas the transects SNORCLE and SC examined younger mountain building processes (e.g., Clowes et al. 1983).

Relating to the ground truth, the strength of exploration seismics, is the Achilles' heel of DSRRP (and seismology). Superdeep drill holes provide the only opportunities of directly correlating observations to the rock properties; the German DEKORP program was able to utilize this in a symbiotic manner.

DEKORP played an important role in the site selection phase of the German superdeep drilling program, KTB, which was set up to drill $\approx 10,000$ m down through an ancient geodynamic suture – see Emmermann and Lauterjung (1997) for an overview of KTB. Later, besides providing a reference point for the seismics at the drill site, the KTB program has yielded direct evidence of shear zones, anisotropy, and substantial amounts of fluids deep in the crust; the analysis of the latter has provided new insights into their origin and role in controlling/influencing geodynamic processes.

The Russian super-deep drilling program in the Kola Peninsula (Smythe et al. 1994) reached the record depth of 12,200 m and also provided valuable *ground truth* regarding the macrostructure of the mature continental crust and the origin of crustal reflectivity.

Upper-mantle reflectivity-frozen subduction has also undergone a paradigm shift as a result of DSRRP investigations. Reflections from upper mantle were already reported by György (1972). DSRRP has provided vivid proof that reflective zones may extend into the upper mantle and has helped understand their structure. Dipping reflectivity in this region has provided information regarding paleotectonics and may – in some cases (see Fig. 4) – be evidence for paleo-subduction (see also BABEL Working Group 1990; Morgan et al. 1994).

Rheology of crust, Moho, and upper mantle depends upon their composition and in situ physical conditions. Intra-crustal faulting, affecting even the Moho, was already inferred by György (1972) and Kanasewich et al. (1969). DSS data from the Indian shield (Kaila et al. 1979) was used by Roy Chowdhury and Hargraves (1981) to infer constraints about the thermo-tectonic evolution of the early earth. With

Deep Seismic Reflection and Refraction Profiling, Fig. 4 Annotated line drawing interpretation of the MOIST profile data, showing coherent reflections from throughout the crustal column. Moho shows up as a more or less continuous boundary. Several dipping thrust-like features (e.g., Outer Isles Thrust) can be seen at all depth

ranges, which also include transparent zones. One dipping reflective zone (Flannan Thrust) is seen to penetrate through the Moho into the upper mantle. (Figure from Finlayson (2010a); see Brewer and Smythe (1984) for details)

Deep Seismic Reflection and Refraction Profiling,

Fig. 5 Unmigrated seismic section from URSEIS profile across southern Urals. (Figure from Diaconescu et al. (1998), with permission from *Geology*). Moho (older than 1 billion years) is bright on the left and is offset sharply in the middle of the figure (Makarovo fault zone) by ≈ 5 km. Migrated image of the boxed upper part (not shown) contains laterally continuous stratification over this fault zone

improved acquisition/processing, such features are now regularly reported from different parts of the world.

(Near) vertical offset in the Moho, inferred at many places from teleseismic, gravimetric, and other geophysical observations, is now often imaged in NMRS. This has important bearings regarding the *nature* of Moho. This first-order seismic boundary is often thought to be a surface that re-equilibrates after tectonic events above (e.g., thrusting) or below (e.g., underplating). DSRRP images contain counter examples too, showing that Moho topography can survive later orogenic cycles, e.g., BABEL Working Group (1990) and Diaconescu et al. (1998). The reason for this behavior is not well understood.

The thermal- and the stress- regimes in the lower crust and upper mantle determine the interaction between the two during the formation of Moho as the boundary layer. Chadwick and Pharaoh (1998) interpret a DSRRP line by associating increased reflectivity of the Moho *there* to its being a detachment surface resulting from low-angle shear (Fig. 6). Local *doubling* of Moho is seen especially in some WARR data – its evolutionary mechanism remains unclear though.

WARR had taken a back seat with the increasing use of NMRS. With progress on some of the processing issues, it has made a comeback following the adage: *structures from reflection and velocities from refraction*. It is, sometimes, a part of onshore/offshore measurements and uses three-component receivers to study crustal anisotropy. Mooney and Brocher (1987) provide a review of earlier coincident WARR studies. Another example is BABEL Working Group (1993). Stand-alone WARR remains useful at places with difficult logistics; see the KRISP experiment in the Kenyan Rift Valley (Khan et al. 1999).

Deep seismic investigations using nuclear explosions: During 1965–1988, the then USSR carried out a series of

very long-range seismic experiments using *peaceful nuclear explosions* (PNEs), supplemented with chemical explosions placed every 100–150 km (Benz et al. 1992). Employing three-component receivers, typically 10 km apart, and recording out to 1550–3000 km (Pavlenkova and Pavlenkova 2006), these datasets provide an invaluable basis for current and future research; QUARTZ, the profile studied most, used 400 three-component receivers, 3 PNEs, and 51 chemical explosions (Morozov et al. [undated](#) IRIS communication; see references); analysis of its data has generated new ideas about wave propagation in the lower crust and upper mantle.

Analysis/modeling of WARR data typically starts by picking *travel times* of first and later arrivals that are interesting, the choice being decided by the data quality and the geological aim. Usually, some prominent (mid) crustal reflected/refracted arrivals are identified and *picked*, along with arrivals from Moho, and possibly deeper ones. Methods of deriving crustal models from this data include ray tracing (Zelt and Smith 1992), tomography (Hole 1992), computation of synthetics, etc. (see also ► [“Traveltime Tomography Using Controlled-Source Seismic Data”](#)). Frequently, a preliminary *velocity model* is iteratively fine-tuned to obtain a desired level of fit to the observed travel times. There are several schemes for *ray tracing*; see ► [“Seismic Ray Theory”](#) and Zelt (1995) for overviews. Of late, amplitude information has also been incorporated in such schemes.

Maguire et al. (2006) contains examples of the different aspects of the procedure in the context of the EAGLE experiment (Fig. 7). Different modeling/inversion schemes yield different results from same input. The DOBRefraction’99 Working Group (2003) provides an example of this. Pavlenkova (2011) has interpreted PNE arrival times to infer upper mantle rheology and suggests layering along the travel paths with boundaries at 100 and 200 km (fluids?).

Deep Seismic Reflection and Refraction Profiling,

Fig. 6 Schematic representation of low-angle shear near Moho (c) with parts of BIRPS seismic sections GRID (a) and NEC (b). (For details, see Chadwick and Pharaoh (1998); figure courtesy of *Tectonophysics*)

Analyzing amplitude of DSRRP signals is a crucial step, to differentiate between competing models of the crust. Improvements in the data quality, and careful processing, allow attempts to quantify the material properties that influence the strength of the recorded signals. Properties that are of primary interest are reflection coefficients (RC) across various boundaries, their variation with the angle of incidence (AVO), and the Q(uality) factor along the path (see ► [“Seismic Data Acquisition and Processing”](#) for definitions). These properties are especially important while considering the probable cause(s) of the bright spots, e.g., fluids, intrusions, layering, etc.

Warner (1990) reported RC values of about 0.1 for lower crustal layers and about 0.15 for Moho – both derived from the WAM profile (Peddy et al. 1989). The polarity (sign) of RC is important in differentiating between likely causes of bright spots sometimes seen in DSRRP images. However,

even using polarity-preserving processing, it is often only possible to determine relative values of RC. ANCORP Working Group (2003) discusses the issues involved for a couple of strong reflectors – *Nazca* and *QBBS* – while reporting $RC > 0.2$ for the latter. Combining NMRS and WARR data, Makovsky and Klemperer (1999) report RC values between -0.3 and -0.4 for the NBS bright spot in the Tibetan middle crust.

Obtaining estimates of Q along the travel path of NMRS signals (relatively high-frequency body waves) is also difficult – the effects due to scattering, conversion, etc. (apparent-Q) cannot be readily separated from the intrinsic attenuation (see also ► [“Seismic Viscoelastic Attenuation”](#)). Combining the two, Hobbs (1990) obtained a value of 500 ± 200 for effective-Q for the lower crust below the WAM profile. Morozov et al. (1998) used the data from the QUARTZ profile mentioned above to obtain a 2D

Deep Seismic Reflection and Refraction Profiling, Fig. 7 Velocity modeling by ray tracing for the EAGLE project (in the Ethiopian rift). Note the variable coverage of the ray tracing (above) and the *smooth* result, with a few long segments, in the final P-wave velocity model

(below) – both these characteristics are typical for WARR data analysis. (For details, see Maguire et al. (2006); figures courtesy of *Geol. Soc. London*, with permission from the author)

Q-model for the upper mantle below this PNE profile down to a depth of 500 km.

Some Recent Developments

DSSRP has traditionally positioned itself between basin-level seismics (using artificial sources) and deep-earth seismology (using natural sources). Recent methodological advances in the above fields have blurred this distinction. This is exhibited by the themes of the biannual meetings:

Seismix-2010: “Seismic imaging of continents and their margins: New research at the confluence of active and passive seismology”

Seismix-2012: “Advances in seismic imaging of crust and mantle: Preface”

Seismix-2016: “Seismic imaging at the cross-roads: Active, passive, exploration and solid Earth”

These may be contrasted with *seismic probing of continents and their margins*, which, with small variations, was used for almost the first three decades.

Note: most submissions at the latest biannual meeting (Seismix-2018) have not (yet) been published but are available at Seismix-2018-abs (2018). These abstracts (56 talks and 48 posters) further show the maturing of DSSRP – both regarding methodology and inclusion of other geophysical data for a better (geodynamic) interpretation.

Improvements in data acquisition are reported in Seismix-2018-abs (2018, pp. 40, 41) using the newly developed DAS (distributed acoustic sensing) technology. Both of these use the data for VSP (vertical seismic profiling) in a mineral exploration setting. Use of OBS (ocean bottom

seismometers) is reported on page 45 of the same abstract collection to improve lower crustal velocity models and also better calibrate pressure measurements from air gun sources.

Noise as a seismic source is now an exciting field of research and is referred to as *seismic interferometry* or *day-light imaging*. The basic idea is that *noise* contains useful information. Noise recorded at two locations can, for example, be used to obtain relevant properties of the intervening medium. See Curtis et al. (2006), Wapenaar and Snieder (2007), and Snieder and Wapenaar (2010) for further details and also ► “Seismic, Ambient Noise Correlation” and ► “Seismic Noise.”

Rawlinson and Goleby (2012) mentioned the use of noise for crustal imaging in their introductory article for Seismix-2010. Ito et al. (2012) use autocorrelation functions of ambient noise to obtain seismic images in a subduction zone. An interesting case of using autonomous recording *nodes* to record noise in between the active recording to obtain better V_s models is reported by Behm et al. (2019).

Inversion – Full/constrained/joint, i.e., the ability to reproduce each wiggle of the seismic observations is the ultimate goal for its interpretation, in terms of the viscoelastic properties of the causative medium (see ► “Seismic, Waveform Modeling and Tomography”); DSRRP benefits from research in this field. For a quick introduction to this topic, including underlying problems, see Virieux and Operto (2009), Virieux et al. (2017), and Brittan and Jones (2019).

True full waveform inversion (*FWI*) of seismic remains an unattained goal, but some progress is reported by, e.g., Górszczyk et al. (2019), which use both OBS and standard multichannel marine reflection data to optimize the crustal velocity model by a joint full waveform inversion. Rawlinson et al. (2016) use a detailed crustal starting model from ambient noise seismics for a *constrained inversion* in teleseismic tomography.

Multidisciplinary studies have been largely not discussed in this entry, which has focused on P-wave measurements. Availability of high-quality *multi-geophysical* data does enable extraction of additional information though. Shear waves, for example, can provide valuable constraints regarding lithology and composition – see Eccles et al. (2011) for an example.

Nowadays, data from other geophysical surveys, e.g., gravity, magnetic, magnetotelluric, geodetic, etc., are frequently available near the DSRRP transects; these can be used to improve both structural and petrophysical interpretation. See Dong et al. (2013) reporting results from the *SinoProbe* Programme (2008–2012) covering deep lithospheric exploration of China.

Integrating diverse geophysical datasets, however, needs special attention during interpretation, to obtain a model which satisfies all data in some optimal fashion. This approach may be further subdivided into *joint assessment* and *true joint/constrained inversion*.

Palomeras et al. (2011) falls in the first category, so does Yegorova and Pavlenkova (2014), who report inverting for density along the PNE profiles, with their starting model taken from seismic data.

Roberts et al. (2012) is an example of attempting to constrain the final model for a multidisciplinary dataset (seismic refraction, MT, and gravity) using computer emulation.

The road ahead will see DSRRP results being increasingly applied to geodynamic problems related to the continental crust/lithosphere (e.g., Seismix-2018-abs 2018, pp. 20, 75). Better acquisition/processing will result in crustal images/properties with a higher resolution, enabling more nuanced conclusions regarding their evolutionary history. Inroads are already being made into more fundamental questions like *earthquake processes* (Górszczyk et al. 2019).

True joint inversion of disparate datasets will remain a challenging problem – not in the least due to the relative scaling for the different datasets. Syracuse et al. (2017) report results from a joint inversion using P- and S-arrival times and dispersion data from Rayleigh waves from USARRAY deployment and Bouguer gravity anomalies. Several important issues related to FWI of different datasets are mentioned by Seismix-2018-abs (2018, p. 58), e.g., optimal acquisition design, large-scale inversions involving *hundreds of millions* of parameters, problem of nonlinearity, and optimizing high- and low-frequency contents of the result.

Research Problems

The massive amount of DSRRP data collected during the past half century has produced many new insights but has also brought up some (yet unsolved) problems.

Origin of crustal reflectivity, clearly visible in DSRRP images of mature continental crust, cannot be explained uniquely. Surface exposures of basement rocks mostly show steep dips due to earth’s surface being stress-free and explain transparent zones at shallow depths. Starting at intermediate depths, these structures are expected to become subhorizontal and seismically imageable and do reveal layering including strongly reflective zones. Smithson and Brown (1977, Fig. 5) had already proposed a *complex* crustal model with a three-fold subdivision based on geo-scientific data. Processes and materials to explain such low- and high-angle deformation, sometimes even affecting Moho and upper mantle, remain a challenge.

Shear zones, decollements, imbrications, laminae, metamorphism (facies changes, mylonitization), sill-like intrusions, and fluids (water, brine, melt, magma) have all been proposed as candidates for crustal (and Moho) reflectivity. Both Kola (Smythe et al. 1994) and KTB (Emmermann and Lauterjung 1997) super-deep drill holes have identified such conditions/structures at depth; extrapolations would point to

the presence of crustal fluids in quantities more than that earlier expected, both in bound and free form. See also Meissner et al. (2006), ► “Continental Crustal Structure” and ► “Crustal Reflectivity (Oceanic) and Magma Chamber”.

Bright spots – zones of very strong reflectivity – present an extra challenge. Pratt et al. (1993) investigated the currency bright spot (Georgia, USA), first assumed to be fluid related due to its flat nature and concluded an (ultra)mafic body instead. Makovsky and Klemperer (1999) inferred 10% (volume) of free aqueous fluids as the cause for the Tibetan bright spot. Figure 8 is an interesting example of two reflective zones, probably with different, but related, origins. Simancas et al. (2003) reported a mid-crustal highly reflective body below SW-Iberia from NMRS observations; later modeling of dense WARR data suggested the presence of high-velocity material. Palomeras et al. (2011) used additional data (heat flow, gravity, etc.) to further study this zone and inferred the presence of sill-like lenses of mantle material.

Origin and nature of (continental) Moho are also not well understood, probably because this boundary – geophysically defined as a first-order transition of P-wave velocity from ≈ 6.8 to ≈ 8.2 km/s – does not always have the same evolutionary history. However, DSRRP has replaced the earlier model for (seismological) Moho, consisting of long refraction segments – more or less flat – by a (seismic) boundary with a complex and variable structure. It seems, at places, to be the equilibrium surface established under the deviatoric stress regime after a tectono-thermal event involving the lower crust and upper mantle. At others, it

seems to be underplated or overlain by sill-like intrusions, from a later magmatic episode. Elsewhere, Moho is only identifiable as the terminal zone of a diffused lower-crustal reflectivity. At many places, it seems to exhibit enough strength, to retain its earlier structure through later tectonic events; examples include *frozen subduction* (Fig. 4) and *offset Moho* (Fig. 5).

Role of (multiple) scattering in lower crust has attracted attention lately – both to explain observations and to relate to geological evidence. Surface outcrops of Moho (read: lower crustal and upper mantle rocks) are extremely rare in the continental setting, e.g., *Kapusking Uplift* (Eastern Canada), *Musgrave Range* (Central Australia), and *Ivrea-Verbano Zone* (IVZ, Northern Italy). While the first two have been studied by DSRRP (LITHOPROBE transect KSZ and Central Australian Basin transect, respectively), IVZ – although sans seismics – has been extensively studied in the past by geologists, e.g., Zingg (1990), and geophysicists, e.g., Berckhemer (1969).

Recently, statistical analyses of detailed geological maps of several exposed (lower) crustal rocks have yielded the tantalizing possibility of a self-similar (fractal) description of their shapes in terms of typical *horizontal* and *vertical scale lengths*. For the IVZ, a 2D von Karman distribution of the structure with bimodal petrology has been derived (Holliger and Levander 1992). Holliger et al. (1993) computed synthetics for such a simulation of IVZ and were able to qualitatively reproduce lower-crustal reflectivity observed in NMRS. At large distances (WARR configuration), the

Deep Seismic Reflection and Refraction Profiling,

Fig. 8 Migrated seismic section from the ANCORP line 2 in the Central Andean subduction zone. (Reproduced from <http://www-app1.gfz-potsdam.de/www/pb3/dekorp/an-fig/Amline2.gif>, with permission from the author). The strongly reflective zone on upper right is the *Quebrada Blanca Bright Spot* (QBBS), and the reflective zone dipping to the right is the *Nazca reflector*. Superimposed red dots show seismicity in this area of active subduction. (For further details, see ANCORP Working Group (2003))

synthetics from the random medium contained laterally correlatable events, which could be erroneously used for velocity analysis, migration, etc., a possibility already suggested earlier (e.g., Levander and Gibson 1991; Emmerich et al. 1993).

Another explanation offered for increased reflectivity in the lower crust, including transition zones, is lamellar structures with associated wave propagation effects (amplitude, anisotropy); see Meissner et al. (2006) and ► “Magnetic Anisotropy.”

Both these possibilities, random heterogeneity and lamination, bring up the role of multiple scattering in the DSRRP wave field and question the propriety of using conventional tools from basin exploration for processing such data. Douma and Roy Chowdhury (2001) used synthetics to show that multiple scattering has a limited effect for a 1D bimodal model of IVZ but also mentioned the need for 2D full-wave numerical simulations.

In the upper mantle too, multiple scattering seems to play an important role. Menke and Chen (1984) had invoked this to explain long-range propagation of P_n -phase from earthquakes. More recently, DSRRP data from PNE profiles, e.g., QUARTZ, has shown surprisingly strong propagation of high-frequency (5 Hz) P_n -phase to distances of 3,000 km!

Estimating descriptive parameters of a possibly random medium in lower crust and the upper mantle can be done by modeling or direct estimation. To explain the long-distance P_n -phase in the QUARTZ data, Ryberg et al. (1995) modeled an upper mantle zone of *horizontally stretched, randomly*

distributed velocity anisotropy. Nielsen and Thybo (2006) modeled a larger dataset (Fig. 9) and inferred random heterogeneity for both lower crust and upper mantle.

Following some earlier work (Hurich 1996; Pullammanappallil et al. 1997; Hurich 2003; Carpentier and Roy Chowdhury 2007), Carpentier et al. (2011) have recently analyzed the data from Line 48 of the LITHOPROBE transect AG statistically. Assuming a 2D *von Karman* medium, they estimated the horizontal scale length of the medium directly from the seismic wave field (Fig. 10), which also shows their interpretation. The comparison with an earlier line drawing-based interpretation (above) illustrates the similarities and differences between the two approaches.

Summary

DSRRP has, over half a century, produced quality images of the continental crust and its margins, revealing their complex structure. These – including some unexpected results, e.g., *frozen subduction* – have contributed significantly to our ideas about the processes, current and ancient, involved in their evolution. As the deep structures, mostly inaccessible, play an important role in the development of the shallower geology, understanding these (*deep faults*) also helps in the optimal exploration of economic resources, e.g., hydrocarbons, ore deposits, etc., and in the study of natural hazards associated with volcanism and earthquakes.

Differential Rotation of the Earth's Inner Core

Xiaodong Song

Department of Geology, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Definition

Differential rotation of the inner core refers to the difference between the rotation of the Earth's solid inner core and the daily rotation of the Earth's crust and the mantle.

Background

Driven by gravity, the Earth differentiated into iron core and rocky mantle at the early stage of its formation. The central core is liquid because of high temperature; but at the center of the Earth, an inner core is formed and gradually grows as the Earth cools, and the liquid iron freezes under tremendous pressure (three million times the atmospheric pressure). The size of the inner core is slightly smaller than that of the moon. Separated from the solid mantle by the fluid outer core, the inner core is thus free to rotate independently under an external torque.

The early idea of inner core rotation came from studies of the geodynamo, which generated the Earth's magnetic field. Gubbins (1981) first suggested that electromagnetic forces between the electrically conducting inner core and the

magnetic field generated in the fluid outer core would cause a differential rotation of the inner core. In a computer simulation of a three-dimensional, self-consistent geodynamo, Glatzmaier and Roberts (1995) predicted that the inner core is driven to rotate by electromagnetic coupling at a few degrees per year faster than the mantle and the crust.

Seismological Observations

Song and Richards (1996) reported first evidence for differential rotation of inner core from seismic observations. The

basic idea of their method is simple. They chose a fixed monitoring station and compare seismic waves that travel through the inner core from earthquakes at the same region but a few years apart. This is like the twinkling of a star, which is caused by disturbance of the light as it passes through the atmosphere (an analogy used by coauthor Paul Richards). The seismic waves used are short-period (about 1 s) longitudinal waves (P waves) that have propagated through the fluid core (generically called PKP waves) (Fig. 1). At the distance range of about 146–154°, there are three possible paths, i.e., PKP (DF) waves that traverse the inner core, PKP(BC) waves that turn at the bottom of the outer core, and PKP(AB) waves that

Differential Rotation of the Earth's Inner Core, Fig. 1 Ray paths of PKP waves and example of waveform doublet used to detect temporal change of travel times through the inner core, (a) Ray paths of three branches of PKP waves turning in the solid inner core (DF), the bottom of the fluid outer core (BC), and the mid-outer core (AB). (b) Highly similar waveforms recorded at one station in Alaska from a waveform doublet from South Sandwich Islands. The two events are 10 years apart, one in 1993 and the other in 2003. (c) Superimposed and enlarged PKP waveforms from the box in (b). The waves through the outer core (BC and AB) are aligned, but the wave through the inner core (DF) shows a small time shift (about 0.1 s). (From Zhang et al. 2005)

turn at the middle of the outer core. The basic data used in detecting the inner core rotation is the time difference between the PKP(BC) and PKP(DF) arrivals, abbreviated as the BC-DF time. Because these two waves travel very closely together in the crust and mantle and in most of the fluid core, the differential time BC-DF is relatively insensitive to uncertainty in source location and to three-dimensional heterogeneities of the crust and mantle along the ray paths. To remove influence of small difference in earthquake location and epicentral distance, the differential time residual is formed by subtracting the observed BC-DF time from the predicted difference for a standard earth model. In addition, residuals of the differential times between PKP(AB) and PKP(BC), which pass through the fluid core only, are used to examine possible systematic biases in source locations.

Song and Richards found that BC-DF residuals along certain paths have changed systematically with time over a few decades. In particular, the seismic waves that emanate from earthquakes in South Sandwich Islands in the South Atlantic travel through the inner core and reach College, Alaska seismic station. They have sped up systematically by about 0.3 s over 28 year-year time interval from 1967 to 1995. They interpreted the temporal change as evidence of an inner core rotation.

The estimate of the rotation rate depends on the underlying aspherical structure of the inner core that results the temporal change from a rotation. The inner core is known to be very anisotropic (i.e., seismic waves traveling through the inner core along different directions have different speeds) (Morelli et al. 1986; Woodhouse et al. 1986; see also review by Song 1997; Tromp 2001). The anisotropy is roughly axis-symmetric with the P-wave speed faster by some 3% along the Earth's rotation axis than along the equatorial plane. However, the anisotropy changes significantly laterally and with depth. The observed temporal change in BC-DF residuals was first interpreted as a change of the orientation of the fast axis of the inner core anisotropy, which yielded a rate of 1.1° per year (Song and Richards 1996), but it was later and preferably interpreted as a shift of lateral velocity gradient in the inner core caused by the inner core rotation (Creager 1997; Song 2000), which yielded a rate ranging from $0.2\text{--}0.3$ to $0.3\text{--}1.1^\circ$ per year.

Subsequent studies provided further support and most estimates of the rotation rate are a few tenths of a degree per year faster than the rotation of the Earth (a super-rotation) (see reviews by Tromp 2001; Song 2003; and Souriau et al. 2003). The methods used include BC-DF times for additional paths (Ovchinnikov et al. 1998; Song and Li 2000; Xu and Song 2003), inner core scattering waves (Vidale et al. 2000), so-called earthquake waveform doublets (Li and Richards 2003; Zhang et al. 2005; see below), and normal modes (Laske and Masters 2003). However, whether the inner core

rotation is real has also been hotly debated because of potential biases such as earthquake mislocation (e.g., Poupinet et al. 2000), failure to detect the motion (Souriau 1998), and discrepancy in the inferred rotation rate (e.g., Creager 1997; Vidale et al. 2000; Laske and Masters 2003).

The most important source of errors is systematic event mislocation. Because global stations used to locate the earthquakes are not exactly the same in different years, the temporal variation could potentially be an artifact of the changes of the station distributions (Poupinet et al. 2000; Souriau et al. 2003). To resolve the debate, the two sides (Dr. Poupinet and the author) worked directly in 2004–2007. A thorough presentation of the collaborative work was published (Sun et al. 2006). The basic conclusion is that earthquake mislocation is too small to explain the observed time shifts in the data, and that inner core rotation is still the best explanation.

Perhaps the strongest support comes from studies of earthquake waveform doublets (Zhang et al. 2005). A waveform doublet is a pair of earthquakes occurring at different times but at essentially the same spatial position, as evidenced by their highly similar waveforms at each station recording both events (Poupinet et al. 1984). Zhang et al. (2005) observed that the waves that traveled through the area outside the inner core, in the crust, the mantle, and the outer core are all the same. Only when they travel through the inner core at different times are they different (Fig. 1). The changes are two folds: first, and most prominently, the PKP(DF) waves (passing through the inner core) move faster in a systematic pattern over time, by about one tenth of a second per decade; second, the PKP(DF) waves themselves change in shape over time, an independent signature for motion of the inner core. The fact that the wave shapes are similar when they emanate from the source region allows them to measure precisely the small time shifts and to pin down precisely where the changes took place. The temporal change of BC-DF differential times for the South Sandwich Islands to College, Alaska path is constrained to be 0.0092 s/year with standard deviation of 0.0004 s/year. The best estimate of the rotation rate is $0.3\text{--}0.5^\circ$ per year faster than the Earth's mantle. Subsequent studies of earthquake doublets suggest that the waves bouncing off the inner core boundary also shows temporal variation (Wen 2006; Cao et al. 2007; Song and Dai 2008).

Concluding Remarks

The discovery of the inner core super-rotation has attracted attention of the academia and popular media. It has implications for understanding the geodynamo and angular momentum transfer in the interior of the Earth (Buffett and Glatzmaier 2000). The origin of the Earth's magnetic field has been regarded as one of the great unsolved problems in

modern physics. The observation of the inner core rotation provides a unique observational constraint on the geodynamo at the center of the earth.

The existence of the differential rotation of the inner core has now generally, although not universally, been accepted. However, major questions remain. What is the acceptable range of the rotation rate? Is the inner core rotation variable? Does the rotation change direction? Does the inner core oscillate within a certain range? The inner core possesses large hemispheric scale variations (Tanaka and Hamaguchi 1997; Niu and Wen 2001). This is difficult to reconcile with an inner core of a constant rotation, which may be expected to average out the lateral varying structure of the inner core over geological time as the inner core grows from the crystallization of liquid iron. If the rotation is variable or oscillating, what is the time scale? What is the driving force? How does it relate to the geodynamo processes? Recently, Lindner et al. (2010) proposed a nonparametric modeling method, which is able to separate mantle structure, inner core structure, and inner core motion. The study suggests an average rate of inner-core rotation of about 0.39° per year and that the rotation has accelerated from about 0.24° to about 0.56° per year within the last 55 years. The speed of the differential rotation, averaging about 10 km per year at the inner core equator, is by 50,000 times the fastest motion of the tectonic plates (20 cm per year) at the Earth's surface. The minimum torque acting on the inner core is estimated 1.19×10^{16} N m, which could easily result from the imbalance of much larger electromagnetic and gravitational torques. With the continuing accumulation of high quality seismic data, I believe we'll reach a new understanding on the inner core motion within next 50 years.

Definition

Earth Solid Earth including oceans and atmosphere.
Earth Temporal variation of the orientation and the
rotation rotation speed of the Earth.

Introduction

The rotation of the Earth or Earth rotation, respectively, specifies the spatiotemporal change of the Earth rotation vector. The direction of the Earth rotation vector corresponds to the instantaneous rotation axis of the Earth and its absolute value equals the rotation speed. The Earth’s rotation is not uniform and is given in terms of Earth orientation parameters (EOP): *precession* and *nutation* are long-term and periodic changes of the direction of the Earth rotation vector with respect to a space-fixed reference system. *Polar motion* is the variation of the direction of the Earth rotation vector with respect to an Earth-fixed reference system (qv ► “[Geodesy, Networks, and Reference Systems](#)”). Changes in the Earth rotation speed are expressed as deviations of *Universal Time 1* (UT1) from the uniform atomic time (*Universal Time Coordinated*, UTC) $dUT1 = UT1 - UTC$ or as variations in the *length of day* (LOD). The subgroup of *polar motion* and $dUT1$ or LOD is called Earth rotation parameters (ERP). Fundamental information on Earth rotation theory and observation and about the relations of Earth rotation variations with geo-

physical processes is given in the seminal works of Munk and MacDonald (1960), Lambeck (1980), and Moritz and Mueller (1987).

While the existence of *precession* was already known to the Greek astronomer Hipparchus in the second century before Christ, *nutation* was not discovered before the eighteenth century by James Bradley. Observations of *polar motion* were taken for the first time by the Bonn astronomer Friedrich Küstner at the end of the nineteenth century by measuring latitude variations. From the 1970s to the twentieth century onward, space geodetic techniques like *Very Long Baseline Interferometry* (VLBI) (qv ► “[Very Long Baseline Interferometry](#)”), *Satellite Laser Ranging* (SLR), *Lunar Laser Ranging* (LLR), *Doppler Orbitography and Radio-positioning Integrated by Satellite* (DORIS), and the *Global Navigation Satellite Systems* (GNSS) like the *Global Positioning System* (GPS) (qv ► “[GPS, Data Acquisition, and Analysis](#)”) have been employed in addition to astronomical methods. Approximately since the year 2000, the latter are no longer routinely applied. Nowadays, the achievable accuracies of the measurements are better than 2×10^{-4} arcsec or less than 0.6 cm, if projected to the Earth’s surface. EOP can be determined from space geodetic observations within the respective parameter estimation process. The transformation between Earth-fixed and space-fixed system and thus the EOP are thereby components of the technique’s observation equation and can be solved for as unknowns. The most precise technique to observe *polar motion* is GNSS, whereas *precession/nutation* and $dUT1$ can be measured directly only by VLBI. Due to the correlation of *nutation* and $dUT1$ with the orbital elements of the satellites, satellite techniques are only sensitive to the time derivation of those parameters, i.e., *nutation rates* and LOD. Promising new devices for the observation of high-frequency variations of the instantaneous Earth rotation vector are large ring laser gyroscopes. These instruments can access absolute rotation by measuring the beat frequency of two laser beams rotating in opposite direction, the *Sagnac frequency* (Schreiber et al. 2004).

Information about the long-term behavior of the EOP is obtained from historical records of lunar and solar eclipses and from the analysis of sedimentary deposition. Evidence for a secular increase in LOD can be found for instance in paleontological studies of coral growth rate.

The observed EOP show a wide spectrum of variations. Its interpretation allows for drawing valuable conclusions about the structure of the Earth and the dynamical features of the Earth's interior, the atmosphere, hydrosphere, and cryosphere. Even anthropogenic influences on Earth rotation such as the impact of mass transfer due to an increased CO₂ emission are subject of scientific investigations (de Viron et al. 2002).

Medium and long-period as well as long-term mass displacements affect Earth rotation (cf. e.g., Gross (2007) or Seitz and Schuh (2010) for a comprehensive compilation and further references). According to the conservation of total angular momentum of the Earth in short terms, the rotation of the solid Earth undergoes variations, which are mirror image to changes in atmosphere and oceans. Any mass variation in one or more components of the system Earth that changes the Earth inertia tensor leads to a corresponding variation in the Earth rotation. One can also think of a mass movement which does not change the inertia tensor, because once a mass element moved away it is replaced by another, like in a circular ocean current. Such a mass transport causes a motion relative to the considered reference frame, which affects Earth rotation as well. In which way changes of the inertia tensor and relative motions can be related to variations in Earth rotation is shown in the successive section.

Mathematical Formulation of Earth Rotation

The dynamical equation of motion of a rotating body with respect to a space-fixed system is given by

$$\mathbf{L} = \frac{d\mathbf{H}}{dt} \quad (1)$$

relating the torque $\mathbf{L}$ acting on the body to the temporal change of its angular momentum $\mathbf{H}$. This is the basic relation for the development of (Newtonian) *precession/nutation* theories, since it describes the motion of the rotating body in a space-fixed reference system. To characterize *polar motion* and changes of the rotation rate of a rotating body, Eq. 1 has to be referred to body-fixed axes, rotating with the angular velocity $\boldsymbol{\omega}$:

$$\mathbf{L} = \frac{d\mathbf{H}}{dt} + \boldsymbol{\omega} \times \mathbf{H} \quad (2)$$

This is one form of *Euler's dynamical equations* for rigid body rotation referred to a body-fixed coordinate system. The angular momentum $\mathbf{H}$ can be expressed as the product of the tensor of inertia $\mathbf{I}$ and the angular velocity vector $\boldsymbol{\omega}$. The inertia tensor is a symmetric matrix containing the moments of inertia and the products of inertia of a rotating body and thus characterizing the mass distribution in the body. Since single particles do not move with respect to the body-fixed system, this tensor is invariant in the case of a rigid body. For a nonrigid (deformable) body, the inertia tensor becomes time variable, and the particles can move with respect to the body frame, thus allowing for relative motions which introduce relative angular momentum. The angular momentum $\mathbf{H}$ of a rotating deformable body is then written as

$$\mathbf{H} = \mathbf{I}\boldsymbol{\omega} + \mathbf{h} \quad (3)$$

with $\mathbf{h}$ denoting relative angular momentum. The first summand is often referred to as *mass* or *matter term*, and the second is called *motion term*. As the Earth is a nonrigid body, the equation of rotational motion 2 has to be extended considering the above stated differences to the motion of a rigid body, leading to

$$\mathbf{L} = \frac{d}{dt}(\mathbf{I}\boldsymbol{\omega} + \mathbf{h}) + \boldsymbol{\omega} \times (\mathbf{I}\boldsymbol{\omega} + \mathbf{h}) \quad (4)$$

These are the *Euler-Liouville equations* or simply *Liouville equations*. The deviations from uniform, rigid rotation are formulated as follows for the rotation vector $\boldsymbol{\omega}$:

$$\omega_1 = \Omega m_1, \omega_2 = \Omega m_2, \omega_3 = \Omega(1 + m_3) \quad (5)$$

where Ω is the mean angular velocity of the Earth. The m_i are small dimensionless quantities describing the excursions of the rotation vector from its uniform rotation due to time-variable changes in the mass distribution of the Earth system and relative particle motion. Assuming the body-fixed axes to be principal axes of inertia and the body to be rotationally symmetric, these mass changes can be taken into consideration by composing the tensor of inertia from constant and time-variable parts:

$$\begin{aligned} I_{11} &= A + \Delta I_{11} & I_{22} &= A + \Delta I_{22} & I_{33} &= C + \Delta I_{33} \\ I_{ij} &= \Delta I_{ij}, & i &\neq j \end{aligned} \quad (6)$$

where the constant parts are the polar moment of inertia C , and the equatorial moment of inertia A of the undeformed Earth and the time-variable components are the quantities ΔI_{ij} . If second-order terms are neglected and the relations 5 and 6 are introduced, the linearized equations of motion can be rewritten as

$$\begin{aligned}
m_1 - \frac{1}{\sigma_E} \dot{m}_2 &= \psi_1, \\
m_2 + \frac{1}{\sigma_E} \dot{m}_1 &= \psi_2, \\
m_3 &= \psi_3 + \text{const.}
\end{aligned} \tag{7}$$

with $\sigma_E = \left(\frac{C-A}{A}\right)\Omega$ being the *Euler frequency*, which would be the frequency of the resonance of a rigid Earth, corresponding to a circular motion of the rotation axis with a period of approximately 305 days. If the Earth is considered to be an elastic or at least deformable body, the *Euler frequency* is replaced by the complex *Chandler frequency* $\sigma_C = \frac{2\pi}{T_C} \left(1 + \frac{i}{2Q}\right)$, with $T_C \sim 433$ days denoting the observed period of the *Chandler wobble* and $Q = 30 \dots 200$ being a dimensionless dissipation factor (see next section for a brief discussion of the *Chandler wobble*). The ψ_i are called *excitation functions*. They contain the changes of the tensor of inertia and the relative angular momenta:

$$\begin{aligned}
\psi_1 &= \frac{1}{\Omega^2(C-A)} [\Omega^2 \Delta I_{13} + \Omega \dot{\Delta I}_{23} + \Omega h_1 + \dot{h}_2 - L_2] \\
\psi_2 &= \frac{1}{\Omega^2(C-A)} [\Omega^2 \Delta I_{23} - \Omega \dot{\Delta I}_{13} + \Omega h_2 - \dot{h}_1 + L_1] \\
\psi_3 &= \frac{-1}{\Omega^2 C} \left[\Omega^2 \Delta I_{33} + \Omega h_3 - \Omega \int_0^t L_3 dt \right]
\end{aligned} \tag{8}$$

The first two equations of 7 for m_1 and m_2 express *polar motion*, while the third equation for m_3 describes the magnitude of the rotation speed and hence LOD variations. Provided that all the time-variable parts of the *excitation functions* (changes of the inertia tensor ΔI_{ij} , relative angular momenta h_i , and external torques L_i) are introduced as known quantities from models or observations, the *Euler-Liouville equations* can be solved for ω . Earth rotation variations can be thus calculated or predicted, respectively, from observed or modeled changes in the components of the system Earth, such as atmosphere or oceans. In general, relative motions (relative angular momenta) contribute more to LOD variations while the major effect on *polar motion* comes from alterations of the inertia tensor. The *excitation functions* are in practice mostly replaced by so-called angular momentum functions, introduced by Barnes et al. (1983). Elaborate explications of the basic Earth rotation formalism can be found in the fundamental books mentioned in the introduction.

Definition and Observation of Earth Orientation Parameters

The elements which are used to perform the transformation between a space-fixed and an Earth-fixed reference system are

commonly referred to as EOP. The realizations of such reference systems by assigning coordinates to selected celestial objects or terrestrial sites, respectively, are called reference frames. The definition and maintenance of the reference frames is one major task of the *International Earth Rotation and Reference Systems Service* (IERS). Conventional reference frames are the space-fixed *International Celestial Reference Frame* (ICRF) and the Earth-fixed *International Terrestrial Reference Frame* (ITRF). The current version of the ICRF is its third realization, the ICRF3 (Charlot 2018). The ITRF2014 (Altamimi et al. 2016) has been adopted as the official terrestrial reference frame and will be followed by the ITRF2020 which is currently under construction. The definition of the EOP actually depends on the kind of the applied transformation method. The IERS recommends the transformation according to the IAU (*International Astronomical Union*) 2000 and 2006 Resolutions (Petit and Luzum 2010). The transformation procedure is defined from the *Geocentric Celestial Reference System* (GCRS) to the *International Terrestrial Reference System* (ITRS) or vice versa. The ICRS is not a geocentric system – its origin is located in the barycenter of the solar system. To transfer from a barycentric system to a geocentric system, effects, which are not directly related to Earth rotation, like aberration and parallaxes have to be taken into account. The orientation of the ICRS however corresponds to the orientation of the GCRS. The transition from the GCRS to the ITRS is described as a sequence of time-dependent rotation matrices:

$$[\text{ITRS}] = \mathbf{W}(t) \cdot \mathbf{R}(t) \cdot \mathbf{Q}(t) \cdot [\text{GCRS}] \tag{9}$$

$\mathbf{W}(t)$ (with “W” for wobble) designates the *polar motion* matrix. It contains the coordinates x_p and y_p of the reference pole CIP (*Celestial Intermediate Pole*) in the Earth-fixed system and the angle s' , which provides the position of the TIO (*Terrestrial Intermediate Origin*) on the equator of the CIP. The TIO and the *Celestial Intermediate Origin* (CIO) realize an instantaneous prime meridian in the respective system. These terms are part of the transformation concept using the *non-rotating origin* (NRO), which replaced the older transformation scheme with ecliptic (plane of the Earth’s orbit) and equator. The rotation between TIO and CIO is performed with $\mathbf{R}(t)$ using a quantity named *Earth Rotation Angle* (ERA). The ERA is directly related to UT1, which is relevant for Earth rotation research. *Precession* and *nutation* are represented by the matrix $\mathbf{Q}(t)$. It comprises rotations around the angles X and Y , the coordinates of the CIP in the celestial system and around the angle s , which locates the CIO on the equator of the CIP. In case of using the transformation according to IAU 2000 resolutions, the five quantities $\{x_p, y_p, dUT1, X, Y\}$ therefore represent the EOP. If

the older transformation concept based on ecliptic and equator is applied, X and Y are replaced by $\Delta\epsilon$ and $\Delta\psi$, *nutations* in obliquity and longitude. The before cited *Celestial Intermediate Pole* is the reference pole measurements of space geodetic techniques are related to. The CIP thus defines the observed axis. This is a pure convention, realized by an accordingly adapted *precession-nutation* theory. The direction toward the CIP does not correspond to any physically defined axis, like the rotation axis, the figure axis, or the angular momentum axis; nevertheless, it is possible to mathematically connect it to each of those axes. Casually, it is often said that Earth rotation observations represent the motion of the Earth rotation axis. Regarding the measurements of space geodetic techniques, this is actually not entirely correct, since they are not sensitive to the instantaneous Earth rotation vector but to the complete rotation matrix only. The CIP defines an intermediate pole, separating the motion of the pole of the ITRS in the GCRS into a celestial part and a terrestrial part. The celestial part (*precession* and *nutations*, $\{X, Y\}$) comprises all motions with periods greater than 2 days, as seen from space. This is equivalent to frequencies between -0.5 and $+0.5$ cycles per sidereal day (cpsd). With the minus sign labeling retrograde motions (opposite to the sense of Earth rotation) and the plus sign labeling prograde motions (in the sense of Earth rotation), all motions outside of the retrograde diurnal band in the Earth-fixed system, i.e., frequencies below -1.5 and above $+0.5$ cpsd, are allocated to the terrestrial part (*polar motion*, $\{x_p, y_p\}$).

The celestial motions, *precession* and *nutations*, are long-term and periodic changes of the direction of the Earth rotation axis or actually of the CIP axis, with respect to a space-fixed reference system, which is realized, for example, by the positions of extragalactic radio sources observed by VLBI. Due to *precession*, the Earth axis moves with respect to the space-fixed system on a cone with an aperture of 23.5° , corresponding to the angle between the Earth's equator plane and the ecliptic. The revolution period amounts to approximately 25,800 years. This time interval is also called Platonic year. The tidal forces of moon and sun are responsible for this steady motion. Since the Earth is not a sphere but can be characterized as an oblate spheroid (qv ► [“Geodesy, Figure of the Earth”](#)) and its rotation axis is inclined by 23.5° with respect to the ecliptic normal, the gravitational torques force the equatorial plane into the ecliptic. Because of its rotation, the Earth acts like a gyroscope and swerves by moving on the abovementioned cone, whose surface can be calculated very precisely.

The smaller periodic change in the direction of the Earth rotation axis that is superimposed to *precession* is called *nutations*. This comprises motions of the Earth rotation axis with respect to the space-fixed system with periods from a few days to 18.6 years, caused by gravitational influences of sun, moon, and the planets of our solar system. *Precession* and

nutations can be modeled and predicted precisely using time-dependent harmonic series expansions. The arguments of the individual harmonic terms are thereby calculated from combinations of five fundamental astronomical arguments. The currently most precise *precession-nutations* model adopted by IAU Resolutions (2000, 2006) is IAU 2006/2000A. In this model, effects of planets, ocean tides, mantle anelasticity, and electromagnetic coupling mechanisms between core and mantle as well as between inner and outer core are considered (Mathews et al. 2002). As for the planets, their direct effect on Earth as well as the indirect effect of the sun acting on a planet, which also causes subtle *nutations* terms, is taken into account. Remaining parts of the axis motion with respect to the space-fixed system that are not covered by the *precession-nutations* model can be measured by means of VLBI and are provided by the IERS as so-called celestial pole offsets. These residuals originate from still deficiently modeled and unpredictable effects, like the *free core nutations* (FCN). The FCN is a proper mode of the Earth, caused by a misalignment of the rotation axes of mantle and core. Whereas first theoretical estimations indicated a period of about 460 days for this mode, VLBI measurements show that the FCN period is more likely to be around 430 days with highly variable amplitude.

The terrestrial part of the change of the direction of the Earth axis or rather the CIP axis is designated *polar motion* (Fig. 1). *Polar motion* has an order of magnitude of several meters and is expressed in a two-dimensional coordinate system by the *pole coordinates* x_p and y_p . According to the definition of the IERS and its precedent organizations, the x -axis is oriented in the direction of the Greenwich meridian, and the y -axis is oriented positively toward 90° west longitude. Already in 1765, the Swiss mathematician Leonhard Euler calculated a circular motion of the pole (of an Earth at that time assumed to be rigid) with a period of around 304 days. Today, we know that *polar motion* is mainly composed from an annual variation and the *Chandler oscillation* or *Chandler wobble*, named after Seth Carlo Chandler who first detected a period of approximately 14 months when analyzing *polar motion* observations at the end of the nineteenth century. The *Chandler wobble* is another proper motion of the Earth with strongly varying amplitude. More precisely, this nearly circular motion is a damped oscillation, which would have vanished due to friction in the Earth's interior after a few decades if there was not a constantly revolving excitation. Although the *Chandler oscillation* is known for more than 100 years, its underlying excitation mechanism is still under investigation. Today, there is broad consensus that the necessary excitation energy emerges from irregular processes in the atmosphere-ocean system (Gross 2000). A radical change in the phase of the *Chandler wobble* around 1925 could also not yet fully be explained. Variations of the Earth's magnetic field are nowadays quoted as potential causes for the phase variations. The interference of the

Earth Rotation, Fig. 1 Polar motion from the combined EOP series C04 14 of the IERS (1962–2019, daily resolution) and position of the mean pole from 1900 to 2017

Chandler wobble and the annual motion leads to a beat-like rising and ebbing of the *polar motion* amplitude to a maximum of 9 m with a beat period of about 6.3 years. The *polar motion* spectrum below 1 year is dominated by irregular variations appearing in 3 and 5 months intervals. The most important short-period variations are due to the ocean tides caused by sun and moon with essentially diurnal and semidiurnal periods (Karbon et al. 2019), albeit the total effect is only about 1/100 of the *Chandler wobble*. Analysis of long-term *polar motion* shows a distinct variation of approximately 11 years. It is usually associated with processes in the Earth's interior but could also be connected to a corresponding cycle of the solar activity. In addition there are other, decadal variations with periods around 30 years and between 70 and

80 years. These are assumed to be caused by geodynamic couplings between Earth's core and mantle. Recently, Adhikari and Ivins (2016) identified terrestrial water storage variability as the source of decadal-like changes in observed *polar motion* during their study period 2003–2015. Secular *polar motion*, i.e., the long-term linear trend in the position of the pole, amounts to about 10.5 cm/year toward Labrador, Canada (e.g., Schuh et al. 2001 or Adhikari et al. 2018). This effect is supposed to be predominantly due to melting of the polar ice masses and postglacial rebound, but also long-term mass movement due to mantle convection is suspected to play a role.

For an extensive review on precession, nutation, and wobble of the Earth, refer to Dehant and Mathews (2015).

LOD is used to express the speed of Earth rotation alternatively to the difference $dUT1$ between UT1, which is directly connected to the Earth rotation speed, and the regular atomic time UTC. The parameter, which is usually quoted to characterize changes in LOD, is actually ΔLOD , the so-called excess LOD which represents the deviation of the effective LOD from the nominal value of 86,400 s (Fig. 2). Variations of LOD can be assigned to different period ranges. In the short-period range with periods from around 1 day and half a day, the strongest influence emerges from the ocean tides caused by sun and moon (Karbon et al. 2018). Hydrodynamic models or altimetry (qv ► “Geoid Determination, Theory and Principles”) provide variations of ocean heights and velocities of the water masses, from which global changes of angular momentum of the world oceans are calculated. These are subsequently used to estimate the oceanic influence on the Earth rotation parameters. In this way high-frequency ERP variations can be predicted from tide and circulation models, and they can already be observed by the high-precision space geodetic techniques mentioned above. In the range of a few weeks to months, periods of ~ 14 and ~ 28 days, due to solid Earth tides (qv ► “Earth Tides”), are dominant. In addition, there are other strong variations between 40 and 90 days basically excited by zonal winds. Seasonal variations due to changes in the angular momentum of the atmosphere show semiannual and annual periods. The variation of LOD with a period of approximately 1 year is predominantly due to annually changing wind patterns. A definite amplification of the annual variation every 4–6 years is associated with large-scale climate signals related to the El Niño phenomenon by which an ocean circulation with a very characteristic pattern in the Southern Pacific is connected to variations of the meteorological parameters. The existence of decadal fluctuations of LOD at the ms level suggests an internal coupling between the Earth's core and mantle exhibiting torques on the order of 10^{18} Nm. Four coupling mechanisms and associated torques are commonly identified, the viscous, topographic, gravitational, and electromagnetic torques. Except for the viscous torque which seems too weak, any of the other

Earth Rotation, Fig. 2 Excess length of day from the combined EOP series C04 14 of the IERS (1962–2019, daily resolution)

torques, would be capable of explaining these LOD variations (qv ► “Core-Mantle Coupling”). Because of tidal friction and long-term mass variations, a secular prolongation of the day by about 1.8 ms in 100 years is observed as well (Stephenson et al. 2016). This is, of course, an average long-term trend deduced from eclipse data over the last 2,700 years. Besides the secular trend, there is also evidence of LOD fluctuations on a timescale of centuries and some indication of an around 1500 years oscillation.

IERS International Earth Rotation and Reference Systems Service

The IERS is an international service for the determination of EOP and their dissemination to interested users. The definition and realization of reference systems for geodesy and astronomy can be regarded as its superior task. According to the terms of reference (Dick and Thaller 2018), the primary objectives of the IERS are to serve the astronomical, geodetic, and geophysical communities by providing the following:

- The International Celestial Reference System (ICRS) and its realization, the International Celestial Reference Frame (ICRF).
- The International Terrestrial Reference System (ITRS) and its realization, the International Terrestrial Reference Frame (ITRF).

- EOP required to study Earth orientation variations and to transform between the ICRF and the ITRF.
- Geophysical data to interpret time/space variations in the ICRF, ITRF, or EOP, and to model such variations.
- Standards, constants, and models (i.e., conventions) encouraging international adherence.

In addition, the IERS collects, archives, and distributes several products such as reference frames, monthly Earth orientation data, daily rapid service estimates of near real-time Earth orientation data, and their predictions. The IERS also announces the differences between astronomical and civil time for time distribution by radio stations and leap seconds which – if necessary to keep the differences $dUT1$ smaller than 0.9 s – are added at midnight of July 31 or December 31. Further products are related to global geophysical fluids such as mass and angular momentum distribution, annual reports and technical notes on conventions and other topics, and long-term Earth orientation information. The IERS began operation on January 1, 1988, as common institution of the IAU and the *International Union of Geodesy and Geophysics* (IUGG) and replaced thereby the former *International Polar Motion Service* (IPMS) and the Earth rotation section of the *Bureau International de l’Heure* (BIH). The service consists, among other parts of a Central Bureau, combination centers of the space geodetic techniques and several product centers, for example, for the collection of data about geophysical influences on Earth rotation (*Global Geophysical Fluids Center*, GGFC). These are atmospheric

and oceanic variations, hydrodynamic effects like groundwater variations, and processes in the Earth's interior which lead to changes in the rotational behavior of the Earth. The Central Bureau is located at the BKG (*Bundesamt für Kartographie und Geodäsie*) in Frankfurt am Main, Germany. Apart from regular publication of EOP, the IERS also issues guidelines (IERS Conventions, Petit and Luzum (2010)), which contain models and standards recommended for the data processing of space geodetic techniques.

Summary

Earth rotation is conventionally described by the EOP, which represent the link between a space-fixed (celestial) and an Earth-fixed (terrestrial) coordinate system. Those EOP expressing the temporal variations of the orientation of the Earth correspond to *precession/nutation* (changes of the direction of Earth rotation axis with respect to a space-fixed reference frame) and *polar motion* (wobbling of the Earth with respect to its axis). Small variations of the speed of Earth rotation are expressed by UT1 minus the uniform atomic time (UTC) or as variations in the LOD. A precise knowledge of the Earth's attitude is needed for all positioning and navigation tasks on Earth and in space. It also gives fundamental information about the interactions between the various geophysical components of system Earth and allows deriving conclusions about phenomena of celestial mechanics. The EOP are nowadays monitored by space geodetic techniques and assembled and published by the IERS.

Earth Tides

John M. Wahr
(Deceased)

Definition

The Earth tide is the deformation of the solid Earth caused by the gravitational attraction of the Sun and moon. The most striking gravitational effects of the Sun and moon are the orbital motion of the Earth's center of mass. The moon causes the Earth to orbit the Earth–moon center of mass, and the Sun causes that center of mass to orbit the Sun.

The Tidal Force

But the Sun and moon also cause points within the Earth to be displaced relative to each other: they cause the Earth to deform. For example, the side of the Earth nearest the moon is attracted toward the moon more than is the center of the Earth. And the side farthest from the moon is attracted less than the center of the Earth. Consequently, both the far and near sides of the Earth are pulled radially outward away from the center. The regions of the Earth that are at right angles to the Earth–moon vector are pulled radially inward.

This deformation pattern is illustrated in Fig. 1. The total gravitational acceleration vectors due to the moon are shown in Fig. 1a. The vectors all point toward the moon, but are of unequal length and direction, although the differences are greatly exaggerated in the figure. The orbital acceleration is, to a high degree of accuracy, equal to the acceleration vector at the Earth's center of mass. Subtracting that vector from the other vectors in Fig. 1a results in the pattern of vectors shown in Fig. 1b. These residual vectors represent that portion of the lunar gravitational force tending to deform the Earth. The residual acceleration field multiplied by the local material density is defined as the lunar tidal force, and the deformation it induces is called the lunar tide.

Note from Fig. 1b that because of the Earth's diurnal rotation the tidal force at a fixed point in the Earth varies through two complete cycles in 1 day; a fixed point rotates through one outward bulge, then through an inward bulge, and then into the other outward bulge, all within a half a rotation period (i.e., within 12 h). This semidiurnal time dependence is split into many periodic terms with frequencies closely spaced about 2 cycles/day, due to the time variability of the orbital motion of the moon. Furthermore, because the moon is not always in the plane of the Earth's equator, there is also significant variability at frequencies

Earth Tides, Fig. 1 All three panels show the Earth as seen from above the north pole. The Earth's diurnal rotation is represented by Ω . The arrows in (a) illustrate the magnitude and direction of the gravitational acceleration toward the moon. The differences in the lengths and directions of the arrows are greatly exaggerated. The lunar tidal acceleration is defined by subtracting the acceleration vector at the Earth's center of mass from the other acceleration vectors. The resulting vectors are shown in (b). The tidal force (the local density times the acceleration) deforms the Earth into the elliptical shape shown greatly exaggerated in (c). Points A and B are used in the text to illustrate tidal strain and tilt

closely spaced about 1 cycle/day (imagine, e.g., that the Earth–moon vector is inclined at 45° to the Earth's rotation axis) and about 0 cycles/day (imagine that the moon is directly above the north pole). The solar tidal force and the solar tide are defined in a similar manner, and can also be decomposed into semidiurnal, diurnal, and long period terms.

For a quantitative description, it is useful to work with the tidal potential, denoted here as V_T and defined so that its gradient is the tidal force per unit mass. Define a nonrotating coordinate system with origin at the center of the Earth. The total lunar gravitational potential at the point $\mathbf{r}$ inside the Earth is (assuming the moon to be a point mass)

$$V = \frac{GM}{|\mathbf{r} - \mathbf{R}|} \quad (1)$$

where M is the mass of the moon, G is Newton's gravitational constant, and $\mathbf{R}$ is the position vector of the moon. Let r, θ, ϕ

be the radial distance, colatitude, and eastward longitude of the Earth-fixed point, $\mathbf{r}$, so that $\phi + \Omega t$ (where $\Omega = 1$ cycle/day is the Earth's angular velocity of rotation) is the azimuthal angle of $\mathbf{r}$ in nonrotating, inertial space. The factor $1/|\mathbf{r} - \mathbf{R}|$ can be expanded as a sum of complex spherical harmonics, $Y_n^m(\theta, \phi)$, so that

$$V = \text{Re} \left[\frac{GM}{R} \sum_{n=0}^{\infty} \sum_{m=0}^n \left[\frac{r}{R} \right]^n d_n^m Y_n^m(\theta, \phi) e^{im\Omega t} \right] \quad (2)$$

where Re denotes the real part (included in Eq. 2 so that the sum over m includes only $m \geq 0$), R is the radial coordinate of the moon, and d_n^m are coefficients that depend on the angular position of the moon relative to nonrotating inertial space. The coordinate R and the moon's angular position depend on time, due to the moon's orbital motion.

The $n = 0$ term in Eq. 2 is a spatial constant and so is physically meaningless. It can be ignored.

The $n = 1$ term represents a spatially constant force, equal to the lunar force at the Earth's center of mass. Consequently, the $n = 1$ term is removed from Eq. 2 when defining the tidal potential V_T .

Since $r \leq a$ where a is the Earth's radius, and since $a/R \approx 1/60$ for the moon (and is much smaller for the Sun), the factor $(r/R)^n$ in Eq. 2 causes the contributions to Eq. 2 to fall off rapidly with increasing n . For most purposes it is sufficient to keep only the $n = 2$ terms in V_T , so that V_T has the approximate form

$$V_T = \text{Re} \left[\left[\frac{r}{a} \right]^2 \sum_{m=0}^2 c_2^m Y_2^m(\theta, \phi) e^{im\Omega t} \right] \quad (3)$$

where $c_2^m (= GM/R(a/r)^2 d_2^m)$ are complex, time-varying coefficients that depend on the orbital coordinates of the moon.

The dominant time dependence in Eq. 3 comes from the $e^{im\Omega t}$ term. This term results in semidiurnal, diurnal, or long period tides, depending on whether m is 2, 1, or 0, respectively. The time-dependent c_2^m in Eq. 3 split the $e^{im\Omega t}$ time dependence into terms with frequencies closely spaced about $m\Omega$.

The Earth's Response

The tidal force causes ocean tides as well as Earth tides. The observed ocean tide is actually the difference between the response of the ocean and the response of the solid Earth. Ocean tides are complicated and difficult to model, for a number of reasons that need not concern us here. Open ocean tides are typically less than 1 m in height, although

ocean tides at some coastal locations can be as large as several meters peak-to-peak.

Earth tides are much easier to understand and model. The tidal force shown in Fig. 1b tends to deform the solid Earth into the elliptical shape shown greatly exaggerated in Fig. 1c. Tidal displacements of the solid Earth are typically several tens of centimeters. But, unlike ocean tides, Earth tides cannot be observed without sensitive instruments. The reason is that Earth tides cause both the ground and the observer to be displaced by the same amount.

One way to detect Earth tides is to use a gravimeter. There are three contributions to the observed tidal variation in the gravitational acceleration: (1) the direct attraction of the Sun and moon, (2) the change in the Earth's gravity field due to tidal deformation within the Earth, and (3) the change in the gravitational acceleration at the gravimeter caused by the radial tidal displacement of the Earth's surface beneath the gravimeter (if the surface moves outward, gravity decreases, and vice versa). All three contributions are roughly of the same order.

The total tidal variation of the observed gravitational acceleration is on the order of 100 μgals or more (1 gal = 1 cm/s²). The unperturbed gravitational acceleration at the Earth's surface is about 10³ gals. So, tides affect gravity at about the 10⁻⁷ level. This is roughly the relative importance of tides on any physical observable, and can be traced to the fact that tidal displacements (a few tens of centimeters) are about 10⁻⁷ of the Earth's radius (about 6×10^8 cm).

A simple, idealized gravimeter is a mass hanging from a spring. The amount the spring is stretched at equilibrium is proportional to the local gravitational acceleration. So by continually monitoring the length of the spring, tidal variations in gravity can be determined. Although real gravimeters are more complicated than this, the basic idea is the same. Most instruments, in fact, do use springs.

To illustrate the effects of tides on gravity, Fig. 2 shows 1 month of hourly gravitational acceleration data as observed with a spring-type instrument at Walferdange, Luxembourg (data courtesy of Olivier Francis). The tides are the dominant signal in the data. The semidiurnal and diurnal tides are especially evident. The longer period (2 weeks and 1 month) amplitude modulations evident in the figure are caused by beating between frequencies separated by 1 cycle/13.7 days and between frequencies separated by 1 cycle/27.6 days. Long period gravity tides have small amplitudes at the latitude of Walferdange, and are hard to distinguish in Fig. 2.

One problem common to all relative gravimeters is calibration. For spring-type instruments, the proportionality

Earth Tides, Fig. 2 One month of hourly gravity data, taken with a spring-type gravimeter at Walferdange, Luxembourg. (Data courtesy of Olivier Francis). The tides are the dominant signal and are described further in the text

constant between the length of the spring and gravity depends on the spring constant, which can never be precisely known. This, for example, could cause errors in the vertical scale in Fig. 2.

Another method of detecting Earth tides is to use a strainmeter. This is an instrument that continually monitors the distance between two points on the Earth's surface, separated by anywhere from a few centimeters to a kilometer. The fact that Earth tides perturb the distance between points can be seen by considering points A and B in Fig. 1c. The distance between those points has been changed by the tidal deformation, because A has moved radially outward more than B. Also, not evident in the figure, A and B have been displaced horizontally by different amounts. Typical tidal variations in the distance between two points are on the order of 10^{-7} times the unperturbed distance.

A third way to detect tidal deformation is with tiltmeters. These instruments measure the tilt of the Earth's surface with respect to the direction of gravity. Tidal tilt of the surface can be understood from Fig. 1c by noting that the tidal bulge has affected the slope of the line between points A and B. The direction of gravity also tips during the deformation, but by a different amount. It is this difference that is observed. Typically, observed tidal tilts are a few tenths of a microradian.

Tidal deformation can also be observed using space geodetic techniques, including satellite laser ranging (SLR), very-long-baseline-interferometry (VLBI), and GPS positioning. These techniques are sensitive to displacements of the ground beneath the observing stations. In fact, one of the primary geophysical objectives of these techniques is to detect tectonic motion of the stations. The effects of Earth tides are evident in the data, but they cannot generally be determined with as much relative accuracy as can the tidal effects on surface gravity, strain, or tilt.

Satellite orbit tracking can also be used to detect tidal variations in the Earth's gravity field. Those variations affect the orbit of a satellite, and so can show up in the satellite tracking data. In fact, for lower-flying satellites the ranging data are usually more sensitive to these tidal gravity variations than they are to tidal displacements of the ground stations.

These various observable tidal effects can be conveniently described, mathematically, by using dimensionless parameters known as Love numbers, defined as follows. The deformation of a spherically symmetric, nonrotating Earth in response to a $Y_n^m(\theta, \lambda)$ applied external potential can be described with that same $Y_n^m(\theta, \lambda)$ angular dependence. Mathematically, this is because the Y_n^m separate spherically symmetric differential equations. The change in the Earth's gravitational potential at $r = a$ (the unperturbed surface of the Earth) and the radial displacement at $r = a$ are both proportional to Y_n^m , and the horizontal displacement vector at $r = a$ is proportional to ∇Y_n^m . The proportionality constants depend on n but are independent of m . Thus, the same constants are pertinent for all three Y_2^m terms in Eq. 3.

Let $\Phi(\theta, \lambda)$, $U_r(\theta, \lambda)$, $U_\theta(\theta, \lambda)$, and $U_\lambda(\theta, \lambda)$ denote tidal effects at the Earth's surface ($r = a$) on, respectively, the Earth's gravitational potential, and the radial, southward, and eastward displacements of the point (θ, λ) . Then, Φ , U_r , U_θ , and U_λ for our assumed spherical Earth have the form

$$\begin{aligned}\Phi(\theta, \lambda) &= kV_T^a(\theta, \lambda) \\ U_r(\theta, \lambda) &= \frac{h}{g}V_T^a(\theta, \lambda) \\ U_\theta(\theta, \lambda) &= \frac{l}{g}\partial_\theta V_T^a(\theta, \lambda) \\ U_\lambda(\theta, \lambda) &= \frac{l}{g\sin\theta}\partial_\lambda V_T^a(\theta, \lambda)\end{aligned}\quad (4)$$

where k , h , and l are the dimensionless Love numbers, g is the unperturbed gravitational acceleration at $r = a$, and

$$V_T^a(\theta, \lambda) = \text{Re} \left[\sum_{m=0}^{\infty} c_2^m Y_2^m(\theta, \lambda) e^{im\Omega t} \right] \quad (5)$$

is the tidal potential (Eq. 3) evaluated at $r = a$.

Tidal variations in gravity, strain, tilt, surface displacements, and satellite orbital motion can all be parameterized in terms of k , h , and l . As one example, consider the gravitational acceleration at a fixed point on the Earth's surface. There are three contributions to this acceleration, as discussed above. First, the direct gravitational acceleration from the moon (or Sun) in the inward radial direction is $-\partial_r V_T(r=a) = -\frac{2}{a} V_T^a$ (using the r^2 radial dependence of V_t shown in Eq. 3). Second, Φ (the tidal change in the Earth's gravitational potential at $r=a$) has an angular dependence Y_2^m and so, outside of the Earth, has radial dependence r^{-3} . Thus, the effect of Φ on the radially inward gravitational acceleration is $-\partial_r \Phi(r=a) = \frac{3}{a} \Phi = \frac{3}{a} k V_T^a$. Third, in the absence of tides, the surface gravitational acceleration, g , varies with radius as r^{-2} . So, if the surface point is displaced radially by U_r , the resulting perturbation in the gravitational acceleration at the displaced surface point is $U_r \partial_r g = -\frac{2}{a} g U_r = -\frac{2}{a} h V_T^a$.

Adding these three contributions together gives the total tidal effect on the observed acceleration as

$$\Delta g(\theta, \lambda) = -\delta \frac{2}{a} V_T^a(\theta, \lambda) \quad (6)$$

where $\delta = 1 - \frac{3}{2}k + h$ is called the gravimetric factor. Similar exercises show that tidal tilt is described by the diminishing factor $\gamma = 1 + k - h$, and that tidal strain, although more complicated than either tilt or gravity, depends on the Love numbers h and l .

The numerical values of the Love numbers depend on the Earth's internal properties. It is possible to learn about some of those properties by comparing tidal observations with predictions based on theoretical results for the Love numbers. For example, tidal observations have been used to place constraints on the Earth's anelastic properties. The effects of anelasticity are frequency- and stress-dependent, but are not well understood. Because tides sample the Earth in unique frequency and stress regimes (at lower frequencies and larger deep-earth stresses than seismology, e.g.), tidal studies have proven useful as complements to other types of anelastic observations.

The use of tides to study the Earth's internal structure can be difficult, for several reasons. One problem is instrument calibration, as described above for gravimeters. Any error in the calibration maps directly into a frequency independent, multiplicative error in the estimated Love numbers.

But there are also a number of other complicating effects, most related to the fact that the Earth is not really spherically symmetric and nonrotating. Some of those effects are potentially useful. For example, the Earth does rotate, and because of that rotation the Earth's internal properties are closer to being elliptically, rather than spherically,

symmetric. In this case, the results of Eq. 4 are still approximately valid, but the Love numbers k , h , and l are notably dependent on frequency near 1 cycle/day. This diurnal frequency dependence is particularly sensitive to the shape of the core-mantle boundary, and so diurnal tidal results can be used to help constrain that shape.

Another omission in the theory described above is the ocean. Tides in the ocean cause time-varying pressure loads on the surface of the solid Earth with the same frequencies as the Earth tides. These loads cause the Earth to deform, and this "load tide" (the tidal deformation that would occur in the absence of oceans is called the "body tide") affects all Earth tide observations to some extent. Tidal gravity observations, for example, can be perturbed by up to 10% near coasts, and typically a few percent in the interior of continents. Tidal tilt and strain can be perturbed by several hundred percent near coasts.

It is often difficult to model and remove the load tide well enough to use the remaining body tide to learn about the Earth's deep interior. There are uncertainties in ocean tide models. Furthermore, the Earth's response to the ocean tides, particularly the contributions to tilt and strain near coasts, can be sensitive to the local material properties that may or may not be adequately known. On the other hand, because of these possible uncertainties, people have sometimes been able to use tidal observations to help constrain the nearby ocean tide or the underlying material properties.

In fact, for tilt and strain local effects can be important on both the load tide and the body tide. By comparing observed tidal amplitudes from instruments in an array of tiltmeters or strainmeters, geophysicists can learn about the local geology and underlying structure. There have even been attempts to look for time-dependent variations in tidal amplitudes near active earthquake faults that might be caused by sudden changes in local material properties preceding an earthquake.

A related problem is that tilt and strain amplitudes are also affected by the local topography and by the shape and size of any cavity the instrument is placed in. (Tiltmeters and strainmeters are often placed in boreholes or tunnels to minimize the effects of the surface environment.) These effects are rarely interesting, and they cannot be observationally separated from the effects of local geology. Instead, they must be modeled separately and removed from the data.

Summary

The effects of Earth tides can be detected in several types of geophysical measurements. These tidal observations can be inverted to learn about large-scale material properties of the Earth's deep interior and about local geological structure.

In practice, a useful inversion is often difficult due to the large number of possible geophysical interpretations, and due to uncertainties associated with instrument calibration, topographic and cavity effects, and ocean tidal loading of the solid Earth.

Earth, Density Distribution

Frank D. Stacey¹ and Paul M. Davis²

¹Division of Exploration and Mining, CSIRO, Kenmore, Australia

²Earth and Space Sciences, UCLA, Los Angeles, CA, USA

Definition

Except for iron meteorites, the Earth is the densest body in the solar system. As has been recognized for more than two centuries, it is, on average, about twice as dense as common surface rocks. But many of the early speculations on its internal structure were bizarre, ignoring the most basic physics and the simplest density information, and prompting a remark in one of the early papers on the subject with a sound scientific base (Oldham 1906): “Many theories of the earth have been propounded ... till geologists have turned in despair from the subject, and become inclined to confine their attention to the outermost crust of the earth, leaving the center as a playground for mathematicians.” Seismological studies,

for which Oldham was one of the pioneers, have changed that by giving us a clear picture of the interior. But debates on many details and improvements in the methods of investigating them continue.

The Mean Density

The first well-informed estimate of the Earth’s mean density was by Isaac Newton, who appealed to four pieces of evidence: the Earth’s surface gravity, the period of the Moon’s orbit, the size of Jupiter, and the orbital periods of its satellites. It was evident to him that the density of Jupiter is a quarter of the density of the Earth. Arguing that the density of Jupiter would not be lower than that of water (it is now known to be 1327 kg m^{-3}), and recognizing that the densest Earth materials would have sunk to the deep interior, he inferred that the mean Earth density is between 5000 and 6000 kg m^{-3} , a remarkable coincidence with the now established value $\bar{\rho} = 5513.4(6) \text{ kg m}^{-3}$. More precise estimates awaited the determination of the gravitational constant, G . Any astronomical or geophysical measurement of gravity, g , or, equivalently the acceleration of a body in a gravitational field, depends on the product of G and a mass. In the approximation of a spherical, nonrotating Earth, mass M , and radius R , as Newton showed, the surface gravity is $g = GM/R^2$ (the departure from this simple equation caused by rotation and ellipticity is about 0.5%). Since g and R have been reasonably well known since Newton’s time, a determination of G is equivalent to a determination of M , or $\bar{\rho}$, and was referred to as such by early investigators. Satellite measurements have given the most precise value of the product $GM = 3.986004415(8) \times 10^{14} \text{ m}^3 \text{ s}^{-2}$, where M includes the mass of the atmosphere, 8.84×10^{-7} of the total.

The first attempts to measure G were by M. Bouguer, who, in the 1730s, was conducting an astrogeodetic survey in the extreme topography of the Andes and noted a plumb line deflection by Mount Chimborazo, in Ecuador. He also compared the gravity on a plateau, at Quito, with observations on the nearby flood plain of the Esmeralda River, the first use of what we now know as the Bouguer method of gravity interpretation. In both cases Bouguer recognized that he was thwarted by heterogeneity of the geological structures and that his estimates of $\bar{\rho}$ were unsatisfactory, but in 1774 his plumb line deflection method was repeated more successfully by N. Maskelyne on the slopes of Mt. Schiehallion in Scotland. Maskelyne’s estimate was revised several times by others, using different assessments of the density of the mountain. This introduced a measure of uncertainty, so that geophysical measurements were generally disregarded for about 50 years after 1798, when H. Cavendish made a series of measurements of the gravitational force between laboratory masses, using a torsion balance developed for the

purpose by J. Michell. However, Cavendish's result was also a subject of doubt. Although the measurements were excellent, the final result was clouded by an arithmetic error, recognized in 1842 by F. Baily, leading to a revival of interest in geophysical methods. The most significant of these was by G. B. Airy, who, in 1856, measured the variation of gravity with depth in a coal mine near Newcastle, in northeast England. Although limited by inadequate measurements of rock density, Airy's experiment was well conceived. It did not require an absolute measurement of gravity but only the differences in its value at different levels in the mine, as indicated by the fractional differences between the periods of pendulums operated by observers who exchanged electrical signals to indicate their timing. The linked variations in gravity and density, recognized by Airy, are central to the development of earth models. The Airy method was used by others for the following 50 years, but with mixed results, and by 1900 the superiority of torsion balance measurements was clear. Now, it appears that conventional balance experiments, pioneered in the late 1800s by P. von Jolly and J. H. Poynting, are better still and the current best estimate of G derives primarily from them: $G = 6.6743(7) \times 10^{-11} \text{ m}^3 \text{ kg}^{-1} \text{ s}^{-2}$. The uncertainty (1 standard deviation), 1 part in 10^4 , is far larger than the uncertainties in the other fundamental physical constants and translates to a similar uncertainty in M , and therefore $\bar{\rho}$, through the very precise value of (GM) .

The Moment of Inertia Constraint

The understanding of the Earth's density structure made little progress, beyond Newton's inference that denser materials would have sunk to the center, until the late 1800s. By then astronomical measurements of precession, combined with astrogeodetic measurements of ellipticity, had given an estimate of the moment of inertia of the Earth, C . This is expressed as a coefficient, f relating C to the mass, M , and equatorial radius, a

$$C = fMa^2 \quad (1)$$

For a uniform sphere $f = 0.4$ and a lower value is a measure of the concentration of mass toward the center. Using recent data the value for the Earth is $f = 0.330968(2)$, with the uncertainty in parenthesis. This number represents a quite strong central concentration of mass and prompted speculation on the Earth's deep composition. The cosmic abundance of iron, apparent from meteorites and the solar spectrum, invited the supposition that the Earth has an iron core. This idea was pursued by E. Wiechert who, in 1897, showed that both M and f could be matched by a model with an iron core and rocky mantle, with both materials approximating their familiar low pressure densities, if the core radius was about

0.78 a . But in 1906 R. D. Oldham reported seismological evidence for a smaller core, with a radius that he estimated to be about 0.4 a (it is now known to be 0.546 a), requiring higher densities for both the core and the mantle. Two developments were needed: recognition of the increase in density by the compression of deep burial and the introduction of a transition zone of increasing intrinsic density within the mantle. Both required more detailed seismological data than were available to Wiechert and Oldham.

Self-Compression

Williamson and Adams (1923) recognized that information about self-compression in a homogeneous layer was available from seismic wave velocities. Using the velocities of both compressional and shear waves

$$V_P = \{[K_S + (4/3)\mu]/\rho\}^{1/2}; V_S = \{\mu/\rho\}^{1/2} \quad (2)$$

they separated the adiabatic bulk modulus, K_S , from the rigidity modulus, μ , by writing

$$\Phi = V_P^2 - (4/3)V_S^2 = K_S/\rho = (\partial P/\partial \rho)_S \quad (3)$$

That is, the seismological parameter Φ gives directly the variation of pressure, P , with density, ρ , in a homogeneous region with an adiabatic temperature gradient. Since $dP/dz = \rho g$, g being gravity at depth z ,

$$d\rho/dz = \rho g/\Phi \quad (4)$$

This is the Williamson–Adams equation for the variation of density with depth in a homogeneous region. An additional term, $-\alpha\rho\tau$, was added by F. Birch to account for a temperature gradient differing from the adiabat

$$\tau = dT/dz - (dT/dz)_{\text{Adiabatic}} \quad (5)$$

where α is the volume expansion coefficient. However, this term is very small except at the limited depths of steep temperature gradients, the lithosphere, and the base of the mantle (D''). In the outer core, it is certainly negligible.

Another reason for imperfection of the Williamson–Adams equation is that, for composite materials, such as mantle rocks that are comprised of several minerals with different properties, there is a frequency dependence of elasticity. The unrelaxed elastic moduli that apply to rapid cycles of low stress, as in seismic waves, are slightly higher than the relaxed moduli applying to strong static compression. Averaged over the lower mantle, the difference is about 0.5% (Stacey and Davis 2008, Table 18.1). This means that $d\rho/dz$ is 0.5% greater than by the Williamson–Adams equation.

Interpreted as an error in the inferred temperature gradient, it amounts to ~ 100 K over the depth of the lower mantle, but earth models are not so accurate that this is regarded as serious.

When self-compression, as represented by the Williamson–Adams equation, is allowed for a simple two-layer model with the observed core size and a rocky mantle cannot match the moment of inertia. It is necessary to bring some mass up higher into the mantle. This was the vital next step to realistic earth models, introduced by K. E. Bullen and B. Gutenberg in the 1930s: the mantle transition zone. By then, seismological information was sufficiently detailed to indicate the depth range of the transition zone and the earth models that followed were quite close to our present understanding. As we now know, the transition zone is a combination of transitions at several levels in the depth range of 220–660 km, where mantle minerals are converted to denser phases. The transition at 660 km is conventionally regarded as the boundary between the upper and lower mantles. The lower mantle, which has two-thirds of the mantle volume and three-fourths of its mass, appears to be more or less homogeneous over almost the whole depth range to the core, at 2900 km depth, and conforms well to the Williamson–Adams equation with a density 18% higher than for the low pressure forms of the minerals. The upper mantle is more complicated. Bullen (1975) reviewed this stage in the development of our understanding of the Earth's density.

Free Oscillation Data

In the 1960s, observations of the Earth's modes of free oscillation introduced a new constraint on the density structure. Whereas body wave seismology gives the ratio K_S/ρ throughout the Earth but provides no formal separation of K_S and ρ , the spheroidal modes involve oscillations in the radial distribution of mass with consequent gravitational as well as elastic restoring forces. The equations of motion and the mode frequencies involve not just the ratios K_S/ρ and μ/ρ but also $G\rho$. With G a known constant, the $G\rho$ term allows an assessment of absolute density independent of elasticity. This is illustrated by considering the frequencies of two modes for the simple case of a uniform solid sphere. The spheroidal mode ${}_0S_2$ is an alternation between prolate and oblate deformations and, since there is radial motion, the $G\rho$ term has an important control on the frequency, f which is given by

$$f^2({}_0S_2) = (2/3\pi)G\rho + (5/3\pi^2)\mu/\rho R^2 \quad (6)$$

whereas the lowest toroidal mode, ${}_0T_2$, is an alternating twist between two hemispheres, with no radial motion and a frequency given by

$$f^2({}_0T_2) = (7/4\pi^2)\mu/\rho R^2 \quad (7)$$

so that

$$G\rho = (3\pi/2)f^2({}_0S_2) - (10\pi/7)f^2({}_0T_2) \quad (8)$$

The frequencies of more than 500 modes have been identified (Masters and Widmer 1995), providing a direct measure of global average properties, including the radial density profile. Fine details, such as the sharpness of boundaries, still require analysis of body wave data, but the broad scale structure is derived from the mode frequencies. The Preliminary Reference Earth Model (PREM) of Dziewonski and Anderson (1981) was produced in this way. It signaled a turning point in seismological studies, with less attention to global average properties and increasing emphasis on lateral heterogeneities, boundary structure, and anisotropy.

A powerful new use of free mode data to clarify the radial density structure was presented by Masters and Gubbins (2003), who selected a combination of modes sensitive to a restricted depth range, rather than inverting the whole data set. By concentrating on a region close to the inner core boundary, they obtained an estimate of the density difference between the inner and outer cores, 820 kg m^{-3} , compared with the PREM difference, 597 kg m^{-3} . The revision amounts to 1.8% of the density at that level, compared with the estimated 0.5% precision of the new technique, and may be interpreted as a measure of the revisions to PREM that may be expected in an updated model. From the splitting of mode frequencies, free oscillation data allow identification of lateral density variations independently of elasticity. This is referred to in a later paragraph on lateral heterogeneity.

A Density Gradient Anomaly

An interesting feature of PREM is the decrease in density with depth in the lithosphere and asthenosphere, over the depth range 24.4–220 km. The obvious interpretation is a steep temperature gradient, but this presents difficulty. The inverted density gradient is slight, little more than 0.1 kg m^{-3} per kilometer of depth, but the difficulty would arise even with zero gradients. For a uniform layer, density is a function only of pressure and temperature, so we can write

$$\begin{aligned} d\rho/dz &= (\partial\rho/\partial P)_T dP/dz + (\partial\rho/\partial T)_P dT/dz \\ &= -0.109 \text{ kg m}^{-3}/\text{km} \end{aligned}$$

and substitute the physical properties of mantle material in this depth range to obtain $dT/dz = 8.6 \text{ K/km}$. (For $d\rho/dz = 0$ this would be 7.9 K/km .) Over the depth range of 195.6 km,

the anomalous gradient gives a temperature range of 1680 K and since the temperature at 24.4 km (the averaged crust-mantle depth of PREM) cannot be taken as less than about 700 K, the implied temperature at 220 km is close to 2400 K. This is about 600 K too high; the temperature at 660 km depth required to meet the (P, T) conditions of the phase transition there is about 1900 K (Boehler 2000) and the 220 km temperature must be lower than that. The discrepancy can be understood if PREM underestimates the effect of anisotropy in the asthenosphere, causing the inverted density gradient as a modelling artifact.

Extrapolation to Zero Pressure and Inferences About Composition

The density profile of PREM, with minor equation of state adjustments, is plotted in Fig. 1, together with equation of state extrapolations to zero pressure and a temperature of 300 K. The extrapolations use equations of state fitted to each of the ranges, assuming that the materials can be decompressed and cooled without phase changes. Thus, the broken line in the figure represents the densities that the high pressure phases would have under ambient conditions. For each of the inner and outer cores and lower mantle, the extrapolated densities are uniform, within the uncertainties of the calculation, and so indicate homogeneity. However, this is not true for the upper mantle, where the model indicates heterogeneity additional to the boundaries that mark recognized phase changes.

The density estimates provide the basic data needed for a discussion of composition. Two long-standing debates that

hang on this are the composition of the core, that is, the light elements that must be dissolved in iron-nickel alloy to reduce its density to that of the core, and the possibility of a significant compositional difference between the upper and lower mantles. As Birch (1952) recognized, there is no plausible alternative to iron as the major core constituent, but the outer core is about 10% less dense than pure iron and Poirier (1994) reviewed the arguments for rival candidate light solutes. At core pressures iron occurs as a hexagonal close-packed (ϵ) phase, for which the extrapolated density would be $\rho_{0,0} = 8352 \pm 23 \text{ kg m}^{-3}$ (Stacey and Davis 2004), compared with the core density, extrapolated to the same conditions and also in the ϵ phase, 7488 kg m^{-3} for the outer core and 7993 kg m^{-3} for the inner core. The effects on the iron density of each of the candidate light elements are known from metallurgical literature; although none of the observations were made on ϵ iron, they are taken as a sufficient guide to their potential contributions to the core density deficit. There are undoubtedly many elements dissolved in the core, but the favored important ones, with the mass percentages required in the outer core if each were the only light ingredient, are H (1.4%), C (10.6%), O (12.7%), Si (17.7%), and S (18.2%). The core densities can, in principle, be explained by any combination of these elements, but geochemical arguments restrict the range. The mass percentages of each, in the inner and outer core, respectively, favored by Stacey and Davis (2008, Table 2.5) are H (0.07%, 0.08%), C (0.45%, 0.50%), O (0.11%, 5.34%), Si (nil, nil), and S (8.02%, 8.44%).

There are two main arguments bearing on the similarity of the compositions of the upper and lower mantles, the seismological evidence for penetration of the 660-km boundary by subducting slabs, and the densities of high pressure phases of mantle minerals. The perovskite phase of $(\text{Mg,Fe})\text{SiO}_3$ is believed to be the dominant lower mantle mineral. It is produced by high pressure laboratory experiments and survives in a metastable state at $P = 0$ provided it is not heated. With no Fe the density at ambient conditions is 4107 kg m^{-3} . The second most important lower mantle mineral is almost certainly ferro-periclase (magnesiowustite), $(\text{Mg, Fe})\text{O}$, which may account for as much as 20% of the composition. It is less dense than the perovskite (3585 kg m^{-3} for MgO) but more readily accepts substitution of Fe for Mg and would be 5956 kg m^{-3} for FeO . The magnesium silicate perovskite can accept Al ions, but neither of these minerals readily accepts Ca, so a calcium perovskite is believed to occur also, but, unlike the magnesium perovskite and periclase, it does not survive decompression and is not as well studied. It is evident that, with a modest iron content, a mixture of these minerals can match the lower mantle density, $\rho_{0,0} = 4144 \text{ kg m}^{-3}$, and that, on the basis of density, there is no evidence for a compositional difference between the upper and lower mantles.

Earth, Density Distribution, Fig. 1 Density profile of the Earth based on PREM (solid line) and the profile of $\rho_{0,0}$, the density obtained by extrapolating to zero pressure and a temperature of 300 K (broken line)

Lateral Density Variations

Convection is ubiquitous in the Earth and this means that lateral density variations, with hot, dilated materials rising, and replaced by denser, cool materials. Heterogeneity of the mantle inferred from body wave tomography is generally consistent with the convective pattern, acknowledging that relics of earlier convective patterns are still apparent, but elastic moduli are more sensitive to temperature than is density and a thermodynamic analysis is needed for interpretation (Stacey and Davis 2008, Sect. 19.7). The splitting of mode frequencies presents evidence of lateral density variations that does not rely on such interpretation, but, in spite of several detailed studies, the difficulties are such that available results must be regarded as preliminary (Ishii and Tromp 1999; Masters et al. 2000; Romanowicz 2001). The general conclusion is that, in addition to temperature variations, compositional heterogeneity of the deep mantle must be invoked to explain the observations, in confirmation of a thermodynamic assessment (Forte and Mitrova 2001; Stacey and Davis 2008, p. 288) of results of body wave tomography (Robertson and Woodhouse 1996; Su and Dziewonski 1997).

With respect to the outer core, observable lateral heterogeneity must be discounted as quite implausible, in view of the speed of convective motion apparent from the geomagnetic secular variation. Compositional layering, with a stable low-density layer at the top of the core has been suggested (Braginsky 1999), but is not generally supported.

Summary

The Earth's density structure is now known in sufficient detail to provide a sound basis for discussions of internal composition. High pressure equations of state (Stacey and Davis 2004), the modern version of finite strain theory, provide reliable extrapolations of density to zero pressure, as well as distinguishing internal heterogeneities caused by temperature variations from compositional and mineralogical differences. Although fine details in the deep interior are not all resolvable, it is evident that the bulk of the Earth does not have very strong lateral heterogeneities, such as are obvious in the crust. Nevertheless, the heterogeneities that are seen are indications of the dynamics of the Earth, making them prime targets for continuing investigation.

Earth's Structure, Core

Lianxing Wen

Department of Geosciences, State University of New York at Stony Brook, Stony Brook, NY, USA

Definition

Structure of Earth's core is referred to as the properties of velocity, density, attenuation, anisotropy, composition, and surface feature of Earth's core and how these properties change with depth, geographic location, and time.

Attenuation is a measure of material's ability to absorb energy as seismic waves pass through it.

Anisotropy is a material property that is directionally dependent.

Mushy zone is a layer of mixing solid inner core and liquid outer core materials.

Overall Structure

The Earth's core occupies the center portion of Earth with a radius of 3480 km. It consists of a liquid outer core and a solid inner core. Earth's core is composed of Fe/Ni and some minor light elements, such as S, C, O, and Si. Those light elements are preferentially enriched in the outer core after the continuing solidification of outer core material to the inner core. Seismic compressional velocity and density exhibit jumps at the inner core boundary at a radius of about 1221 km. The inner core is anisotropic in both velocity and attenuation, with seismic waves exhibiting higher velocities and higher attenuation as they propagate along the polar paths than along the equatorial paths. In first order, the inner core exhibits an east-west hemispheric difference of various seismic properties, a

change of anisotropy with depth, an irregular surface, some localized mushy zones at the top, and temporal change of its surface in a time scale of days or months (Fig. 1).

Radial and Lateral Variations

With possible exception at the bottom and the top, the outer core is homogeneous due to vigorous mixing of the liquid iron/nickel. The inner core exhibits complex lateral and radial variations of structure, with the most prominent feature being the hemispheric difference in seismic velocity, attenuation, and anisotropy, between the "eastern" hemisphere (defined between longitudes from 40°E to 180°E) and the "western hemisphere" (defined between longitudes from 180°W to 40°E). The eastern hemisphere exhibits a higher velocity, higher attenuation, weaker anisotropy, and a larger transitional depth from top isotropy to deep anisotropy. The top 235 km of the eastern hemisphere also exhibits a flat velocity gradient with depth. At depth, the innermost 300 km of the inner core may have different forms of anisotropy from the rest of the inner core.

Earth's Structure, Core, Fig. 1 Cartoon summary of east-west hemispheric differences in seismic properties (velocity, attenuation, and anisotropy), surface topography, and mushy zone in the Earth's inner core

Irregular Surface

The inner core surface is irregular, despite that its global feature is not yet clear. In the regions that have been studied by seismology, most regions exhibit flat topography. But in some localized regions, the inner core surface exhibits at least two scales of topography: a height variation of 14 km changing within a lateral distance of no more than 6 km and a height variation of 4–8 km with a lateral length scale of 2–4 km.

Mushy Zone at the Top

A localized 4–8 km thick mushy zone is discovered across the inner core boundary beneath southwest Okhotsk Sea, with seismic properties intermediate between those of the inner and outer core and of a mushy zone. The discovered localized mushy zone is surrounded by a sharp inner core boundary nearby.

Temporal Changes

In some localized regions, mostly beneath Africa, South America, and central Pacific, the inner core surface changes its radius by several kilometers in a time scale of days or months. The temporal change of inner core surface appears episodic, rapidly migrating, and alternatively enlarged and shrunk.

Possible Physical Mechanisms

The proposed physical mechanisms for explaining the inner core structure include:

- (1) *For the inner core anisotropy*: solidification texturing due to the growth of inner core material and preferential alignment of anisotropic Fe crystals caused by inner core convection, magnetic force, and preferential growth of the inner core in the equator
- (2) *For the east-west hemispheric features*: a mantle-induced inner core solidification and a self-sustained translational inner core with the eastern hemisphere melting and the western hemisphere solidifying
- (3) *For the temporal change of inner core surface and inner core topography*: small-scale variation of temperature and/or composition near the inner core boundary and deformation of inner core surface by small-scale force near the inner core boundary
- (4) *For the mushy zone*: the current outer core composition being close to eutectic in most regions resulting in a sharp inner core boundary, but deviation in some localized regions generating a mushy zone

Earth's Structure, Global

Jean-Paul Montagner

Seismological Laboratory, Institut de Physique du Globe, University Paris-Diderot, UMR CNRS/7154, Paris, France

Definition

Structure of the Earth	The manner in which the Earth is constructed. It is characterized through physical and chemical parameters.
Crust	The outer layer of the solid Earth that lies above the Mohorovicic discontinuity.
Mantle	A thick layer of rock below the crust down to the core-mantle boundary CMB at 2,900 km depth.
Core	The central part of the Earth below CMB. It is composed of the fluid outer core (2,900

	down to 5,100 km) and the solid inner core below.
Anelasticity	Property of a substance in which there is no definite (linear) relation between stress and strain.
Anisotropy	Property of a substance being directionally dependent, as opposed to isotropy (identical properties in all directions).
Tomography	Imaging technique of 3D objects, developed in medical sciences, astrophysics, geophysics, etc. It is based on the use of large density of penetrating waves illuminating the object. The images are displayed as 2D cross sections (in Greek, “ <i>tomos</i> ” means slice) of the object.

Introduction

The Earth is the largest in size and mass of the Solar System's four terrestrial planets. Of these four planets, Earth also has the highest density, the highest surface gravity, the strongest magnetic field, and fastest rotation. It is also the third planet from the Sun and the densest and fifth largest of the eight planets in the Solar System. Earth is a terrestrial planet, meaning that it is a rocky body, rather than a gas giant like Jupiter. Earth is currently the only place where life is known to exist and the only terrestrial planet with active plate tectonics.

Earth Sciences in general, and Geophysics in particular, are built on the foundations of physics, mathematics, geology, and astronomy and are closely connected to other disciplines such as chemistry and biology. Its roots therefore go far back in history, but the science has blossomed only in the last century with the impressive increase in our ability to measure the properties of the Earth and the processes in play inside the Earth, on and above its surface. Geophysics includes the study of the Earth's solid layers, fluid envelopes, and near-space environment. However, in this contribution, the subject is narrowed to the solid Earth.

The interior structure of the Earth, like that of the other terrestrial planets, is divided into layers by their physical (rheological) or chemical properties. Scientific understanding of Earth's internal structure is based on geological, geochemical, and geophysical observations at the surface of the Earth including topography and bathymetry, observations of rock in outcrops, and samples brought to the surface from greater depths, primarily by volcanic activity. Geophysics can make use of measurements of different physical fields such as the gravity, magnetic fields, and the fields associated with the propagation of seismic waves passing through the Earth. The Earth's gravity field can be used to calculate its mass, its moment of inertia. By adding some additional

physical constraints, the density variations within the Earth can be calculated. The magnetic field of internal origin provides fundamental information on the deepest layer of the Earth, the core (see contributions by Foss, “Magnetic Data Enhancements and Depth Estimation” and Arora, “Magnetic Methods, Principles”). This interdisciplinary observational approach is complemented by laboratory experiments with minerals at pressures and temperatures characteristic of the Earth's deep interior.

The technological advances of the last century in laboratory and field instrumentation, computing, and satellite-based remote sensing are largely responsible for the explosive growth of geophysics. These advances enabled geophysicists to make more and more accurate measurements, to collect and to analyze enormous amounts of data, and to model more and more complex systems. This new view of how the Earth works enabled a fundamental understanding of structure of the Earth as well as earthquakes, volcanoes, and mountain building, indeed all of geological processes and objects.

1D Structure of the Earth

The global structure of Earth can be defined in two different ways, either by considering its physical properties or its chemical properties. Geophysics is the only Earth science discipline enabling to image the invisible deep inner structure of our planet by a direct measurement of its physical properties. To first order, the structure of the earth is dominated by its radial structure (spherically symmetric model). During the first part of the twentieth century, geophysicists determined the onion-like fine structure of the Earth. Seismic waves enable to investigate the elastic and to some extent anelastic properties of the whole Earth.

Characterizing the Interior of the Earth with Earthquake Waves

Global seismology started in 1889 when Ernst von Rebeur-Paschwitz in Potsdam (Germany) associated a disturbance recorded on a tiltmeter with the occurrence of a remote Japanese earthquake. Since then, seismologists modeled the propagation of seismic waves from teleseismic events by using the ray theory considering seismic waves as virtual particles following rays between earthquake focus and receivers, and their travel times are sensitive to the structure of the Earth.

During the first decades of the twentieth century (see Dziewonski and Romanowicz (2015) for details), the layering of Earth was indirectly inferred using the travel times of refracted and reflected seismic waves generated by earthquakes. The changes in seismic velocity of P-waves (compression waves) and S-waves (shear waves) between

different layers causes refraction owing to Snell-Descartes's law. Reflections are caused by a large increase in seismic velocity and are similar to light reflecting from a mirror. Seismologists were able to find and characterize the main seismic discontinuities (depth and velocity jump) within the different layers of the Earth (see Vinnik, this issue). First of all, the Mohorovicic discontinuity between crust and mantle in the depth range 10–60 km then the core-mantle boundary at 2,900 km depth by Oldham (1906). The core does not allow shear waves to pass through it, showing that its outer part is fluid. Finally, Inge Lehmann (1936) demonstrated the existence of a solid inner core.

Mantle itself can be divided into upper mantle and lower mantle by a discontinuity at 660 km depth. In the upper mantle, the finding of a discontinuity around 410 km depth defines the “upper transition zone” between 410 and 660 km depth. At the base of the mantle, about 200 km above the core-mantle boundary, a discontinuity was discovered, identifying the still mysterious D”-layer. There are some other candidates for entering the club of seismic discontinuities, the Hales discontinuity at 80 km depth, the Gutenberg discontinuity at the base of continental and oceanic lithosphere, the Lehmann discontinuity at 220 km, and also at 520 km and around 900 km depths, but their global nature is still debated. The layer between 660 km and 900 km is commonly named the “lower transition zone.” Most seismic discontinuities are interpreted as a mineralogical phase transition between minerals of mantle silicates (olivine-perovskite system), but some of them might be a boundary between different chemical compositions.

From its elastic properties, the different layers are presented in Table 1 and Fig. 1. The Earth can be divided into the outer silicate solid crust, the upper mantle (including lithosphere, asthenosphere, and upper transition zone), the lower mantle (with the lower transition zone and the

D”-layer at its base), the liquid outer core much less viscous than the mantle, and the solid inner core.

From 1D Models to 3D Tomographic Models

Many reference models (spherically symmetric models) have been developed during the last century, but the most popular ones are the PREM (Preliminary Reference Earth Model by Dziewonski and Anderson 1981) (Fig. 2) and IASP91 (Kennett and Engdahl 1991). PREM introduced for the first time an anisotropic layer (with the specific case of radial anisotropy with a vertical symmetry axis) in the uppermost 220 km of the mantle. Montagner and Kennett (1996) by trying to reconcile body wave and normal mode data showed that a significant amount of radial anisotropy is also necessary in the mantle transition zones between 410 and 900 km depth.

However, important deviations between observed and theoretical travel times of seismic waves with respect to 1D-reference models cannot be explained by these simple 1D models. These differences, though relatively small (<10%), are due to the existence of lateral heterogeneities of physical properties within the different layers of the Earth. Since the 1960s, the acceptance of the paradigm of plate tectonics and mantle convection leads the seismological community to a better appraisal of the coupling between lithosphere and the underlying mantle convection. Plate tectonics demonstrated that the internal dynamics is very active and that tectonic plates are the surface evidence of deeper convective phenomena. According to geodynamics calculations, large lateral variations in temperature must be associated with lateral variations of seismic velocities. This new approach of global geodynamics has been facilitated by the revolution of broadband seismology in the 1980s (see Engdahl, this issue), which came up with the rapid expansion of seismic networks, the free accessibility of digital data, and more and more powerful computers. Time was ripe for the new era of seismic tomography (imaging of 3D seismic anomalies) and its application to global geodynamics.

Earth's Structure, Global, Table 1 The 1D structure of the Earth

Layer (Kilometers)	
0–80	Lithosphere (locally varies between 5 and 200 km)
0–35	Crust (locally varies between 5 and 70 km)
35–80	Uppermost part of mantle
35–2,890	Mantle
35–660	Upper mantle
80–220	Asthenosphere
410–660	Upper transition zone
660–2,890	Lower mantle
660–900	Lower transition zone
2,740–2,890	D”-layer
2,890–5,150	Outer core
5,150–6,360	Inner core

Mantle Convection Jigsaw

The investigation of mantle convection is the best example of the implementation of these new available tools in the framework of an interdisciplinary approach. Thermal convection in the Earth has been recognized for a long time (Holmes 1928; Pekeris 1935) as the cause of dynamic processes such as mountain building, volcanic and seismic activity, and, more recently, seafloor spreading. With the advent of plate tectonics, it has become possible to describe quantitatively the motions at the surface of the Earth. The plates, considered as rigid bodies, are the surface manifestation of deep-seated movements related to mantle convection (e.g., Turcotte and Schubert 2002). This evidence constitutes the first manifestation of peculiarities of mantle convection, for it demonstrates large variations in the rheological properties of Earth material between rigid plates and underlying mantle, which cannot be explained by 1D models. Meanwhile, hotspots were identified (Wilson 1963) and their fixity with respect to plate motions demonstrated (Morgan 1971). There is a good consensus on the origin of plumes in a thermal boundary layer, but the depth of origin of hotspots is still controversial. The rheology of the lithosphere and the existence of hotspots are two simple examples which illustrate the fact that mantle convection differs in many respects from "classical" convection (such as Benard convection) observed in usual viscous fluids.

The understanding of mantle dynamics is similar to a police investigation: each earth science field provides miscellaneous and often contradictory clues, which must be assembled like jigsaw puzzle pieces. Different approaches

have been used to characterize and understand mantle convection (see ► "Mantle Convection" in the chapter by Bercovici, this issue). None of them could provide a general and consistent explanation of simple features such as the shape and geometry of plates, the origin of hotspots, the number of layers in the mantle, etc. Many questions arose: How is surface geology (continents, plate boundaries, mountain ranges, hotspots) reflected at depth? How are interactions and the coupling between the different layers of the Earth characterized? How does deep mantle flow affect the surface geology, or conversely how do surface phenomena affect deep dynamics?

Another issue was the characterization of the spatial scales of heterogeneities at the global scale. Geology makes evident a multiplicity of scales. Some tectonic plates are gigantic (larger than 10,000 km), some others smaller (1,000 km). Continents have as well various sizes. The different plate boundaries (subduction zones, ridges, transform faults) have a very small lateral extent (a maximum of 100 km except continent-continent collision zones). Hotspots are even smaller and their role in global geodynamics cannot be explained by plate tectonics. This multiscale approach is also present for the temporal scales. Whereas times associated with plate tectonics count in tens of millions of years, catastrophic events such as hotspot birth, mantle avalanches, and seismic and volcanic cycles last only centuries. According to time scales, rheological properties change. Therefore, natural phenomena are by essence multiscale and make it necessary a multidisciplinary approach. The role of geophysicists consists in quantifying, understanding

processes, and proposing simple laws in spite of the complexity of processes.

One of the most powerful approaches to investigate mantle convection is the numerical approach. The basic equations of physics governing mantle convection are well known (Navier-Stokes equations and thermal equation of energy conservation). This system of equations is very complex and nonlinear, expressed in terms of adimensional numbers such as the Rayleigh number Ra . Actual estimates of Ra make it largely beyond the critical Rayleigh number, which means that mantle convection is thermally turbulent. In other words, mantle convection is chaotic at the geological time scales, meaning that the convective flow is not stationary in time and space. With the rapid expansion of computer facilities, it is now possible to numerically simulate the equation system. However, it turns out difficult to reproduce plate behavior with numerical experiments. Laboratory experiments complete the whole numerical battery, enabling to finely investigate some specific phenomena. Material science, by studying physical properties of earth minerals (rheology, anelastic and elastic properties) at very high pressure (by using diamond anvil cells and synchrotrons, etc.), also provide important information on mineralogical composition of the mantle. Most seismic discontinuities can be interpreted as pressure- and temperature-induced phase changes in the olivine system (Birch 1952), such as the 410 km and 660 km discontinuities. However, some composition changes might also occur around these depths and deeper in the lower mantle where thermochemical convection might be predominant. The recent and unexpected discovery of the post-perovskite (high-pressure phase of magnesium silicate) in 2004 (Murakami et al. 2004; Oganov et al. 2004), present in the lowermost mantle, has fundamental influence of the convective mixing in the deep mantle, particularly in the D''-layer.

In that context, the determination of 3D models of seismic parameters of the mantle (also coined tomographic models) can be considered as a pragmatic approach which consists in imaging the structure of convection in order to provide clues to the nature of driving mechanism and to investigate mantle convective processes, the engine of plate tectonics. Thanks to the intensive use of computers which can handle very large data sets, the techniques of seismic tomography (Nolet 2008) can image the 3D deep structure of the Earth and provide unavoidable constraints of possible models of mantle convection and makes it possible to test different competing hypotheses. However, the main limitation of seismic tomography is that it only provides an instantaneous image of our planet Earth, and it is necessary to confront seismic results with other Earth science fields providing information on the history of our planet.

Seismic 3D Tomography: The Earth Scanner

Seismic wave propagation is very sensitive to temperature, chemical, and mineralogical anomalies. These anomalies reflect the active dynamics of the Earth which should be a dead planet without them. It was observed for many decades that seismic velocity below old continents is much larger than the velocity beneath young oceans. This difference between tectonic provinces can be explained by a different history: cratons older than one billion years had a lot of time to get colder, whereas below oceans, the younger and warmer lithosphere is permanently recycled within the mantle. An increase in temperature is usually translated into decrease in seismic velocity, whereas an increase in pressure is translated into velocity increase. At a given depth (approximately constant pressure), the lateral variations of seismic velocity can be primarily interpreted in terms of temperature variations. A large variety of tomographic techniques similar to ultrasonography or scanner has been developed for getting the 3D structure of the Earth, notwithstanding the geological nature of the surface.

The first 3D models of the Earth's mantle were proposed by the end of the 1970s (Dziewonski et al. 1977; Sengupta and Toksoz 1976), but the true revolution of seismic tomography took place in the mid-1980s when a complete set of tomographic models was proposed from the surface down to the center of the Earth (see Woodhouse and Dziewonski (1984); Nataf et al. (1994); Tanimoto and Anderson (1985) for the upper mantle; Dziewonski (1984) for the lower mantle). The present lateral resolution at global scale for the whole Earth is approximately 1,000 km. Tomographic models (Fig. 3) fundamentally renewed our vision of Earth dynamics and shed new light on deep processes.

At 100 km depth, the distribution of seismic velocity anomalies reflects the geological surface structure. Almost all plate boundaries are slow since they are often associated with active volcanism. In oceanic zones, seismic velocity increases with the age of the sea floor confirming the cooling of plates with age. This remarkable agreement between observed seismic structure and structure deduced from geology was the first proof of the validity of tomographic approach. At larger depths, the correlation between surface geology and seismic structure progressively vanishes and the amplitude of seismic anomalies decreases. The continental roots can be found down to 250–300 km, but mid-ocean ridges are no longer visible. In contrast, subducting slabs associated with high velocities can be traced down very deeply. The upper and lower transition zones (410–900 km) are still one of the less well-resolved depth range. It is characterized by weak heterogeneities, but the velocity distribution is dominated by a simple scheme, with high

Earth's Structure, Global,
Fig. 3 Maps through S-velocity models SAW24B16, SB4L18, TXBW, and S20RTS and P-velocity models P-MIT and FF-PRI at depths of 125, 600, 1,350, and 2,750 km. (From Thurber and Ritsema 2015)

velocities around the Pacific Ocean and slow velocities below central Pacific and Africa, the so-called “degree 2” pattern (Masters et al. 1982).

At the global scale, it is usual to expand the velocity anomalies in terms of spherical harmonics $Y_l^m(\theta, \phi)$, where θ, ϕ are the spherical geographical coordinates, l the angular degree, and m the azimuthal order. The spectral amplitude of individual degree l enables to assess the importance of different spatial wavelengths λ , since λ is inversely proportional to l . The “degree 2-pattern” predominant in the transition zone as well as in the D”-layer is associated with large-scale mantle flows, upwellings on both sides of Pacific and upwellings below central Pacific and Africa. The spectrum of heterogeneities is “red” (see Dziewonski and Romanowicz 2015 for a review), therefore dominated by very large wavelengths, but the role of smaller scale objects such as slabs and mantle plumes is still discussed.

The behavior of slabs in regional studies does not seem to be uniform (Fig. 4a). Some slabs seem to fall down to the core-mantle boundary (van der Hilst et al. 1997), whereas others, e.g., beneath Japan (Fukao et al. 1992), are stagnant in the transition zone. Mantle plumes and the associated hotspots might initiate continental breakup, inducing the opening of new ridges of oceans, and might dramatically affect biodiversity. After plate tectonics, plume tectonics? There is still a controversy on the origin of plumes. It is likely that they do not have a single origin but can originate from the different boundary layers within the Earth, in the asthenosphere, transition zones, and D”-layer. There are still lively debates about the origin at depth of mantle plumes (Fig. 4b shows an example of plume imaging), and two opposite extreme models (plate model and plume model) are summarized in Fig. 5. At the base of the mantle, the D”-layer is still very mysterious since it is the probable

graveyard of slabs and a good candidate for being the matrix of some mantle plumes giving birth to hotspots at the surface of the Earth.

An Anisotropic and Anelastic Earth

Most earth minerals cannot be limited to their isotropic and elastic properties. When they are deformed over geological timescales, mineral grains and aggregates tend to align by crystal preferred orientation (CPO) which can lead to bulk anisotropy (see “► Magnetic Anisotropy”). Additional anisotropy can also come up when crack distribution (in the crust) or fluid inclusions (asthenosphere, inner core) are present within the material (shape preferred orientation, SPO). Water content might also play a key role in alignment mechanisms (Karato et al. 2008). In the upper mantle, the different minerals present are strongly anisotropic. The difference of velocity between the fast axis and the slow axis is larger than 20% for olivine, the main constituent of the upper mantle. Other important constituents such as orthopyroxene or clinopyroxene are anisotropic as well (>10%) (see Babuska and Cara (1991), Anderson (2007), and Mainprice (2015) for reviews). Consequently, the petrological models which are assemblages of different minerals are less anisotropic than pure olivine. The amount of anisotropy is largely dependent on the percentage of these different minerals and on the mechanisms aligning the crystallographic axes according to CPO. For example, the anisotropy of the pyrolytic model, mainly composed of olivine and orthopyroxene (Ringwood 1975), will depend on the relative orientation of the crystallographic axes of different constituents (Christensen and Lundquist 1982).

For the sake of mathematical simplicity, it was usually assumed that the propagating elastic medium is isotropic, in spite of the large amplitude of anisotropy in several depth

Earth's Structure, Global, Fig. 4 Tomographic images of slabs (Top, van der Hilst et al. 1997) and plumes (Bottom, French and Romanowicz 2015)

Earth's Structure, Global,

Fig. 5 Competing models for explaining the origin of hotspots (Left, Courtillot et al. 2003; Anderson 2001). (From Foulger et al. 2005)

ranges. And only 1D reference models of attenuation are incorporated in seismic modeling. Global tomographic models improved over the years not only by an increase in the number of data but also by more general parameterizations. They are now including anisotropy (radial anisotropy in Nataf et al. (1994); general slight anisotropy in Montagner and Tanimoto (1991)) and anelasticity (Romanowicz 1995). Whereas isotropic heterogeneities enable to map hot and cold regions within the Earth, seismic anisotropy gives access to the convective flow. Gaboret et al. (2003) and Becker et al. (2003, 2008) demonstrated that mantle circulation inferred from geodynamic models is in good agreement with radial and azimuthal anisotropy distributions (Fig. 6). Seismic anisotropy has many other applications such as the determination of the base of continental roots (Montagner 1994; Gaherty and Jordan 1995; Silver 1996; Gung et al. 2003; Debayle et al. 2005) and the investigation of small-scale convection at the base of the lithosphere and of convection boundary layers within the Earth, in the transition zones (Trampert and van Heijst 2002), D"-layer (see Lay and Garnero et al.), and even within the inner core (see Souriau and Calvet 2015 in structure of the inner core).

Because of its strong dependence on temperature, partial melting, and water content, mapping anelastic attenuation in the Earth has the potential to provide valuable information on Earth's three-dimensional (3D) structure and dynamics, in complement to what can be learned from mapping elastic isotropic velocities and anisotropic parameters. A significant challenge is to separate the effects of anelastic (or intrinsic) attenuation from those of elastic focusing and scattering (or extrinsic) due to propagation in elastic 3D structure.

Seismic anisotropy and anelasticity provide new ways to investigate geodynamic processes within the different layers of the Earth.

Outlook: New Challenges

So far, global 3D-tomographic models are well resolved for very large spatial scales (>1,000 km). And the global flow circulation in most of the mantle is dominated by the "degree 2 pattern." However, smaller wavelengths are not so well resolved even though many geological objects with a lateral

Earth's Structure, Global,

Fig. 6 Numerical modeling of flow circulation superimposed to 3D tomographic model (Gaboret et al. 2003)

extent of the order of 100 km, such as slabs or mantle plumes, play a key role in global geodynamics.

New innovative numerical techniques for forward modeling (such as Spectral Element Method) and for inverse problems (adjoint tomography of Tarantola 1986; Tromp et al. 2005) are now available and make it possible to use the full waveforms of seismograms. The first images of different volcanic plumes including Hawaiian plume (Montelli et al. 2004) were first obtained by incorporating finite frequency effects (see ► “Seismic Tomography”). Therefore, a new revolution in global tomography is underway (see Fig. 4b for images of plumes).

Impressive progress through global tomography, geochemistry, and mineral physics has been made during the last 30 years in our understanding of global geodynamics, demonstrating how active and turbulent is our planet. All layers are heterogeneous, interact, and exchange matter. The geosciences community must improve the lateral resolution and the quality of the 3D images and incorporate on a routine basis anisotropy and anelasticity. There is a real need for a 3D seismic reference Earth model in agreement with geological and mineralogical data and fluid dynamics modeling.

This progress brings about the expansion of new instruments such as very dense seismic networks on land (e.g., US array, Hi-Net, Euro-Array, etc.) and on the sea floor, by exploring other planets and by incorporating new data

such as seismic noise (Shapiro et al. 2005; Nishida et al. 2009) implementing more powerful numerical techniques. Geophysics only provides some pieces for our puzzling global geodynamics, and a multidisciplinary effort is necessary to fully understand the spatiotemporal evolution of our planet. The exploration of other telluric planets is necessary for having other examples of solutions chosen by nature, and the seismometer within InSight mission successfully deployed in January 2019 on planet Mars will provide such answers.

velocity province (LLSVP)
Ultra low velocity zone (ULVZ)

beneath the Atlantic Ocean and Africa. They are continental-sized in lateral dimension, and up to and over 1000 km high. A ULVZ is a thin (tens of kilometers thick) and isolated (100–1000 km laterally) structure with very low seismic wave speeds.

Introduction

Earth's interior has three fundamentally distinct divisions: (1) the relatively buoyant and thin outer crust, which averages roughly 6–7 km in thickness beneath oceans and 30–40 km in continents; (2) the mantle, which extends to nearly half way to Earth's center; and (3) the dominantly iron (Fe) core, which has a fluid outer part and a solid inner part. Figure 1 highlights these basic shells, along with a number of additional significant mantle subdivisions. The mantle is divided into an upper and lower part, with the boundary near 660 km depth. The

Deep Earth; Deep mantle

Definition

Seismic Tomography An inverse method that utilizes seismic wave travel times and/or waveforms to estimate Earth's seismic velocity and density structure, either regionally or globally.

Forward Modeling The procedure involving the generation of models that predicts observations, which is frequently used in deep Earth seismology.

Phase Transition A crystallographic rearrangement of atoms in a mineral that occurs at high pressure.

D'' The depth shell of Earth occupying the lowermost 200–300 km of Earth's lower mantle. (Pronounced “D-double-prime”)

Large low shear Two LLSVPs exist at the base of the mantle, one beneath the Pacific Ocean, and one

FIGURE 1

upper mantle has another distinct discontinuity near 410 km depth. As shown in Fig. 2, the dominant mineral in the upper mantle is olivine, a magnesium-iron silicate mineral with composition $(\text{Mg,Fe})_2[\text{SiO}_4]$, that undergoes phase transitions to higher density mineral forms (or polymorphs) near 410, 520, and 660 km depths. The region between 410 and 660 km is referred to as the mantle transition zone. Below 660 km, mantle silicates undergo another phase transformation, compacting into the perovskite structure (recently given the mineral name bridgmanite) with composition $(\text{Mg,Fe})[\text{SiO}_3]$, plus magnesium-iron oxides, $(\text{Mg,Fe})\text{O}$ (known as ferropericlase and also referred to as magnesiowüstite in earlier literature). In the lowermost several hundred kilometers of the mantle, a region referred to as D'' , perovskite has been shown to undergo an additional phase transition into the “post-perovskite” structure (Murakami et al. 2004), and depending on the temperature, post-perovskite might back-transform into perovskite at greater depth, remaining as perovskite down to the CMB (see *The D'' Layer* encyclopedia entry). The lower mantle depth shell accounts for nearly 56% of Earth's volume, and extends from 660 km depth down to the core-mantle boundary (CMB) at 2891 km depth (and thus includes the D'' layer). The major discontinuities throughout Earth's mantle are thus well-explained by phase transitions in the olivine-perovskite system.

While uncertainties are present in our understanding of the exact compositional makeup of Earth's mantle, it is generally believed that bridgmanite is the dominant mineral structure of the lower mantle, possibly accounting for ~80% of the lower

mantle, and hence is the most abundant mineral on Earth. This perovskite mineral structure is the same as that occurring in well-known electronic and piezoelectric materials, such as barium titanate. A fundamental difference between the silicate minerals of the upper mantle and lower mantle perovskite is that every silicon (Si) atom in perovskite is surrounded by six oxygen (O) atoms (silicon is octahedrally coordinated), whereas for upper mantle silicates the silicon is bonded to four O atoms (tetrahedral coordination). Thus a primary effect of the higher pressure in the lower mantle is that O atoms occupy a smaller volume, thus more can be organized around (coordinated with) Si. This more compact rearrangement of atoms in lower mantle phases means that they have higher density than upper mantle materials, as well as differences in other properties such as the material's stiffness and resistance to shearing. These changes affect the velocities of seismic waves; thus, at depths where phase transitions occur, there are jumps (i.e., discontinuous increases) in seismic compressional and shear wave speeds (referred to as P-wave and S-wave velocities, or V_P and V_S , respectively). Velocity and density depth distributions in Earth's mantle are presented in Fig. 2; these values represent an estimation of the globally averaged properties.

The exact depth of a phase transition in any given mineral group depends upon temperature and pressure (and chemical composition). Earlier conceptions of the lower mantle (Birch 1952) postulated that the lower mantle had a constant composition, and hence the temperature and velocity variations could be described by simple adiabatic compression.

Earth's Structure, Lower Mantle, Fig. 2 (a) Variations in seismic properties of the Earth's mantle with depth, from the surface to the core-mantle boundary, showing the major discontinuities in P-wave velocity, S-wave velocity, and density. (b) Mineralogical makeup of the mantle. Cpx, clinopyroxene; Opx, orthopyroxene

However, in light of more recent studies, it is interesting to consider the fact that lateral temperature variations are likely in the lower mantle, because the mantle is convecting, and hence phase boundaries are not expected to be perfectly flat (e.g., Lebedev et al. 2002). Rather, they should have relief that directly relates to the temperature field (or to perturbations in chemical composition, since minerals may transform at different pressures if there are variations or impurities in the mineral composition). The Earth presumably was significantly hotter in the distant geologic past (from heat generated during formation and differentiation of the mantle and core), and therefore we expect phase boundaries in the earliest Earth to have been at different depths than today.

Tools for Studying the Lower Mantle

Earth's mass and moment of inertia, determined from orbital and rotational dynamics, provide important information about the planet's internal density distribution. These data, combined with assumptions about starting materials for Earth's formation from analyses of meteorites, have long indicated a predominantly iron core with a silicate rock mantle (Carlson 2003). Seismic studies early in the twentieth century confirmed the existence of the core (outer and inner), as well as the fact that the outer core is liquid (from the absence of shear waves on the opposite side of the planet following an earthquake, because shear waves cannot propagate in fluids).

A number of Earth science disciplines contribute to our body of knowledge of the lower mantle (and the deep Earth in general). For example, the field of mineral physics includes high pressure laboratory experiments aimed at simulating the pressures and temperatures within the deep Earth. Predictions of the melting temperature of iron at the conditions of the boundary between the inner and outer core (at radius of ~1220 km), as well as measurements delineating the temperature of the olivine to bridgmanite plus ferropericlase phase transition at 660 km depth, provide two important temperature tie-in points that help to constrain Earth's geotherm; temperature must be extrapolated from these points toward the CMB, where a very large temperature jump occurs. Based on such studies, the top of the lower mantle at 660 km depth is at a pressure of about 23 GPa (1 Pa = 1 N m⁻² and 10⁵ Pa corresponds to approximately 1 atmosphere of pressure) and a temperature of about 1800 ± 200 K (e.g., Ito and Katsura 1989; Frost 2008). The CMB is at a pressure of about 130 GPa; the temperature, while less constrained, has been estimated to be about 4000 ± 500 K (Boehler 1996; Van der Hilst et al. 2007) but recently lower values have been proposed (Nomura et al. 2014). The temperature jump from the CMB to the outermost core may be as much as 1000–1500 K.

A number of notable uncertainties are present that currently preclude precise knowledge of lower mantle

temperature, including the amount of heat-producing radioactive materials, the vigor of mantle convection, the heat flux from the fluid core into the mantle, and important thermal properties of bridgmanite at lower mantle pressure and temperature conditions (e.g., thermal conductivity, heat capacity, and the coefficient of thermal expansion). However, using a diamond anvil cell high pressure-device to achieve pressures as great as those of the lower mantle and even the core, researchers have recently refined our understanding about two important characteristics of bridgmanite. As mentioned above, bridgmanite (*br*) can transform into a higher pressure (and density) structure termed “post-perovskite” (*ppv*) at D'' pressures (around 120 GPa). Thus, if the systematics of this phase transition can be well defined from laboratory experiments or theory, then seismic mapping of the *br*→*ppv* transition depth (as well as that of possible *ppv*→*br* back-transformation) adds an additional temperature tie-in point for the geotherm (Hernlund et al. 2005). Another discovery describes a change with increased pressure in the electronic spin state of iron in magnesiowüstite and perovskite (a change from a high spin configuration with a maximum number of unpaired d-shell electrons to a low spin configuration in which d-shell electron pairing is maximized). Experiments indicate that this will occur between the depths of 1000 and 2200 km (Lin et al. 2013; Badro 2014). Current research predicts that this spin transition may result in a softer material, which can thus be more compressed and increase the density of the deeper mantle, possibly affecting convective dynamics as well as seismic velocities, element partitioning, and oxidation state (Shim et al. 2017; Liu et al. 2018).

The vigor of mantle convection plays a central role in the cooling of Earth. The most commonly used parameter to determine if convection is occurring and to describe the strength of convection is the Rayleigh number, *Ra*:

$$Ra = \frac{\alpha g \rho \Delta T D^3}{\eta \kappa},$$

where α is the coefficient of thermal expansion, g is the acceleration due to gravity, ρ is density, ΔT is the non-adiabatic temperature change across the convecting layer (in this case, the whole mantle) of thickness D , η is the viscosity, and κ is the thermal diffusivity. *Ra* in the lower mantle is estimated to be on the order of 10⁷; values greater than ~10³ indicate that convection is occurring and values as high as 10⁷ indicate convection with motions on the order of cm per year, which is considered quite vigorous when considered over geologic timescales. Furthermore, factors such as the temperature dependence of viscosity can strongly affect the style of convection, causing warmer regions to undergo significantly more strain than cooler regions. Thus, numerical convection calculations incorporate our best understanding of Earth's properties and provide important information

about the dynamics and evolution of the mantle (and planet as a whole).

Erupted materials offer an opportunity to study mantle chemistry. Specifically, some hotspot volcanoes are thought to be caused by mantle plumes that originate in the lower mantle. However, it is possible that not all hotspots tap the lower mantle, and instead have different depths of plume source origin (Courtillot et al. 2003). It is widely accepted that lavas from hot spot volcanoes are enriched in incompatible elements and often have a higher $^3\text{He}/^4\text{He}$ ratio than lavas erupted at mid-ocean ridges. This has led to a view that the lower mantle contains a distinct reservoir (or multiple reservoirs) that has undergone only limited stirring with the upper mantle (Hofmann 1997). Subsequent and ongoing work continues to challenge and extend that perspective (Jackson et al. 2017; Stracke et al. 2019). We address geodynamic issues in the “Three-Dimensional Structure and Dynamics” section below.

Seismic imaging is the primary tool that gives us the ability to map lateral variations of mantle properties from the upper mantle to the CMB. Seismic tomography provides an image of the full three-dimensional heterogeneity field, albeit at relatively long horizontal wavelengths, on the order of 1000 km and greater (e.g., Kustowski et al. 2008; Ritsema et al. 2011; French and Romanowicz 2015). Variations in seismic velocity as well as density (e.g., Trampert et al. 2004; Ishii and Tromp 2004; Koelemeijer et al. 2017) have been mapped, and have important implications on convective flow in the interior.

Information about the small-scale heterogeneity field has been provided by a number of forward modeling seismic studies. For example, some studies have suggested that small-scale scatterers (~ 1 km) exist throughout the lower mantle (Hedlin and Shearer 2000). Other studies find evidence for discrete reflectors in some locations, particularly beneath subduction zones (e.g., Rost et al. 2008; Frost et al. 2018). The exact nature of such small-scale heterogeneity is unknown, but may indeed relate to an incompletely mixed mantle, or heterogeneities entrained from the top (dense things falling) or the bottom (buoyant things rising).

Three-Dimensional Structure and Dynamics

For decades it has been known that Earth's mantle contains significant lateral variations in seismic properties, which are due to variations in temperature and/or chemical composition compared to the local average properties. Results from seismic tomography depict V_P , V_S , and ρ changes throughout the mantle. Variations are neither expected nor detected in the fluid outer core; the extremely low viscosity and relatively fast convection promote homogenization (Stevenson 1987). Seismically detected mantle heterogeneity is the strongest in the outermost few hundred kilometers of the mantle (i.e., near

the planet's surface), due to the strong variations in temperature and composition associated with plate tectonic and mantle convection processes (Masters et al. 2000). The next most seismically heterogeneous depth shell is the D'' region at the base of the mantle (see Encyclopedia entry on *The D'' layer*). Figure 3 shows seismic velocity variations in the lower mantle. D'' silicate rock is juxtaposed against the fluid iron outer core, which represents roughly a 75% increase in density. Thus the mantle side of the CMB can accommodate long-lived stable structures over a wide range of densities (between the mantle and core density); it is possible that cumulates denser than average lowest mantle silicates can survive entrainment by the convective currents in the overlying mantle (e.g., McNamara and Zhong 2005; Garnero and McNamara 2008; Garnero et al. 2016). However, other possibilities are viable (Deschamps et al. 2007; Schubert et al. 2009; Davies et al. 2015).

The lower mantle above D'' displays variability in seismic properties, but at a much weaker level than that imaged at the top and bottom of the mantle. In some regions it is plausible that low amplitudes of mid-mantle heterogeneity may reflect our limited ability to confidently image the mantle there (due to a lack of seismic information because earthquakes and seismic recorders are not uniformly distributed on Earth). Nonetheless, all seismic tomography studies to date agree that heterogeneity is greater at the top and bottom of the mantle relative to the middle of the mantle.

Plate tectonics involve the creation of plates at mid-ocean ridges, and destruction or consumption of plates at subduction zones, where the cold and dense oceanic crust and lithosphere (compared to the surrounding mantle) descend into the interior. Tomographic analyses have shown that lineations in high velocity wave speeds beneath subduction zones (e.g., Grand et al. 1997; Li et al. 2008; Obayashi et al. 2013) are consistent with cold material subducting deep into the lower mantle. While the penetration depth of subducting slabs is not adequately constrained beneath all subduction zones, it is widely accepted that many slabs descend through the 660 km discontinuity, in some cases reaching to the CMB (such as beneath the Caribbean). It is important to understand the large-scale long-term flux of material from Earth's surface to great depths in the interior because of the importance for long-term (geological time) effects on surface volatiles, the atmosphere, and global climate.

The amount of mass flux between the upper mantle down into the lower mantle depends on several poorly known quantities such as the viscosity of the descending slab and mantle, the viscosity increase at the 660 km discontinuity, a possible viscosity increase in the upper lower mantle near 1200 km depth (Rudolph et al. 2015), as well as the degree of viscous coupling between the oceanic lithosphere and underlying asthenosphere (before and after subduction). Time-integrated mass transfer into (and out of) the lower mantle

Earth's Structure, Lower

Mantle, Fig. 3 Tomographically derived shear velocity heterogeneity in the lower mantle (French and Romanowicz 2015) is shown for four positions of the globe. Heterogeneity has been iso-surfaced (red) in the lower half of Earth's mantle at the -0.75% level. The two large low shear velocity provinces (LLSVPs) are present

plays a role in long-term mixing and lower mantle residence time of deep mantle minerals. For example, weak viscous coupling between slabs and the surrounding mantle predicts lower flux rates into (and out of) the lower mantle, and hence less mixing between the upper and lower mantle. A strong coupling between the slab and mantle predicts the opposite. Uncertainties in current data and predictions result in difficulties in distinguishing between these possibilities.

An analogous dependency between mixing and convective parameters exists for the bottom of the mantle, where recent work argues for large low shear velocity provinces (referred to as LLSVPs) being compositionally distinct from the surrounding mantle (Cottaar and Lekic 2016; Garnero et al. 2016; Deschamps et al. 2019; Roy et al. 2019). Convective currents associated with subduction sweep basal dense material to regions away from downwellings, forming thermochemical “piles” (Fig. 4) (McNamara and Zhong 2005; McNamara et al. 2010). The contrast in properties (e.g., density, viscosity, temperature) between piles and surrounding mantle will determine the morphology and vertical extent of the pile material, as well as the degree of entrainment (and

hence its evolutionary behavior). The two nearly antipodal large low shear velocity provinces, or “LLSVPs” (Cottaar and Lekic 2016; McNamara 2019), one beneath the central Pacific and the other beneath the southern Atlantic and Africa (Fig. 3), are accompanied (in certain areas) by low velocity conduits that are associated with mantle plumes (e.g., Montelli et al. 2004), which appears to correlate with the surface locations of hotspots and reconstructed origination locations of large igneous provinces (Burke et al. 2008; Torsvik et al. 2010). Thus the present-day large-scale structure and circulation pattern of the lower mantle represent a time-integrated effect of anomalous temperature and/or chemistry in Earth's lowermost and uppermost mantle boundary layers (D'' and the lithosphere, respectively).

At smaller scale lengths, seismic studies have found evidence for seismic wave scattering. The imaged size of heterogeneities in the lower mantle ranges from kilometer to tens of kilometers in scale (e.g., Vidale and Hedlin 1998; Wen and Helmberger 1998; Frost et al. 2017). This observation indicates chemical anomalies at a spectrum of physical scales and a mantle that is not fully mixed. Indeed, analyses of magmas

(a) Chemically distinct regions: mantle (blue), lowermantle reservoirs (pink), and ultra-low velocity zones at the core-mantle boundary (red)

(b) Temperature variations cooresponding to (a)

Earth's Structure, Lower Mantle, Fig. 4 Numerical geodynamics calculations for a model mantle consisting of three distinct chemistries are shown for the whole mantle, from Earth's surface to the core-mantle boundary. Panel (a) displays the chemical field, showing the bulk of the upper and lower mantle in blue, as one chemistry type, dense lower mantle piles (pink) as a second distinct chemistry, and thin ultra-low

velocity zones at the core mantle boundary (red) that accrue near the pile margins. (b) The temperature field associated with (a) is shown. Red and blue are hotter and colder regions, respectively. The dense piles can be stable for billions of years, though a low level of entrainment is constant, as evidenced by the white streaks throughout the mantle in panel (McNamara et al. 2010)

from hot spot volcanoes have yielded characteristic isotopic signatures distinct from those of mid-ocean ridge basalts, arguing for unique, possibly isolated deep mantle reservoirs that feed mantle plumes. Irregular convective patterns (e.g., see Fig. 4) are consistent with such heterogeneities spreading through the lower mantle as well as being entrained into mantle plumes, but not necessarily in a systematic fashion (since convection patterns appear multi-scaled and may be complex). Alternatively, scattering of seismic energy can occur from small pockets of partially molten mantle material. This scenario has been motivated by the detection of thin (a few kilometers) laterally discontinuous layers right at the CMB, called ultra-low velocity zones (ULVZs). ULVZs have been argued to contain some degree of partial melt, and hence offer a plausible source of scatters composed of melt pockets (whether or not they are of a distinct chemical composition). Subduction of oceanic crust into the deep mantle also

represents a viable source of lower mantle heterogeneity (e.g., Li et al. 2014; Mulyukova et al. 2015).

Future Progress

As seismic sensors are deployed in new regions across Earth's surface, new geographical regions will be sampled with greater certainty, and thus our understanding of global processes will greatly improve. As sensor deployments become denser (with smaller distances between sensors), Earth's deep structure can be imaged with a much greater resolution. Thus, small-scale structures and processes can be inferred with greater certainty and tied to estimations of global processes. The seismic work only maps present-day structure, which must be put in a dynamical and evolutionary framework (e.g., Hernlund and McNamara 2015) with the predictions

from geodynamical convection calculations, which in turn must first be informed by an understanding of the material properties. The latter comes from the field of mineral physics, both in laboratory experiments at high temperature and pressure and with computer simulations of material behavior at the atomic scale. The time evolution of Earth is also informed by geochemical analyses of erupted materials and meteorites. Thus, future work that advances our understanding of the structure, dynamics, and evolution of Earth's interior will be multidisciplinary in nature.

Summary

Earth's lower mantle represents the largest volume of any depth shell on Earth. It is unique in that its chemistry, structure, dynamics, and evolution represent a time-integrated effect of the chemistry and dynamics of the surface (lithosphere, asthenosphere) and lowermost mantle (D'', ULVZ, LLSVP, and CMB) boundary layers. The degree to which the lower mantle is recycled into the upper mantle depends upon many poorly known convective parameters, such as the viscosity and viscous coupling of descending slabs, as well as material properties, such as the nature and origin of plausibly dense deep mantle chemically distinct piles. Future work of improved seismic imaging coupled with continued advancements in other deep Earth disciplines, such as geodynamics, mineral physics, and geochemistry, will greatly help to reduce uncertainties in our understanding of Earth's evolutionary pathway, and present-day structure and dynamical state.

Earth's Structure, Upper Mantle

Guust Nolet

IRD Geoazur and Université Côte d'Azur,
Sophia Antipolis, France

Definition

The upper mantle is defined as that part of the mantle between the crust and the phase transition of γ -olivine to perovskite. The total mass of the upper mantle is 1.06×10^{24} kg, about a quarter of the total mass of the mantle. Its volume, 2.95×10^{11} km³, is a third of the total volume of the mantle.

Until the discovery of a major transition near 660-km depth, the upper mantle was better known as Bullen's "layer B," extending to 400-km depth. A sharp gradient or discontinuity in seismic velocity causes a bend in the travel time curves of P-wave arrivals near 20°, such that the slowness drops from more than 12 s/deg. to 10 s/deg. This phenomenon was observed as early as 1931 by Jeffreys, who correctly adopted a suggestion by J.D. Bernal that it represents a high-pressure modification of olivine. The modern notion of the upper mantle actually extends into Bullen's next layer, "layer C," which has now been abandoned as a physically meaningful subdivision.

The depths to the top and the bottom of the upper mantle cannot be given precisely because they depend on the region. The Mohorovičić discontinuity marks the transition from the crust to the upper mantle, with a density jump of the order of 10%. It is found at very shallow depth near ocean ridges where oceanic crust is formed but extends to more than 70-km depth beneath the Himalayas and the Andes. The “transition zone” between upper and lower mantle is marked by the transition of olivine (Mg_2SiO_4) to its polymorph β -olivine (Wadsleyite) near 410-km depth to γ -olivine near 520-km depth and finally to perovskite (MgSiO_3), which occurs near a depth of 660 km, but with variations of ± 20 km depending on temperature and composition and possibly with variations more than twice that large for narrow areas inside hot plumes and cold slabs. A typical temperature estimate for the phase transition gives a temperature of about 1600 °C at 660-km depth. The upper mantle is one to two orders of magnitude less viscous than the lower mantle, and its electrical conductivity is much lower, with the possible exception of regions of partial melt.

The upper mantle itself is subdivided into several depth regions, characterized by their differences in density, mechanical properties, and/or seismic velocity:

Lithosphere It is a strong layer with a viscosity of the order of 10^{21} Pa s and a thickness typically about 80–150 km, though it may exceed 200 km beneath old cratons, representing the rigid “plates.” The temperature gradient is strongly superadiabatic. The geotherm in the lithosphere connects the low temperature at the bottom of the crust, 600–900 °C under continents but as low as 250 °C in the oceans, to the (approximately adiabatic) temperature in the asthenosphere (1200–1300 °C).

Gutenberg discontinuity The transition between lithosphere and asthenosphere, historically known as the Gutenberg discontinuity, is defined as the depth where shear velocity starts to decrease with depth. The most likely cause is that the weakening effect of temperature exceeds the effect of pressure at this depth. However, where it is sharp the rock composition, melt and/or the presence of water must also play a role. Sharp transitions may be mapped using receiver functions, in which case the boundary is often denoted as the lithosphere–asthenosphere boundary or LAB. Byrnes et al. (2015) discuss the various options for this LAB.

Asthenosphere It is a mechanically weak layer with low viscosity of the order of 10^{19} Pa s. This layer is present under the oceans and the younger part of continents, but its existence beneath the oldest cratons is uncertain. It may contain a small degree of partial melt.

Lehmann discontinuity It is a positive velocity jump named after Inge Lehmann who first observed this feature beneath

Europe and North America near 150-km depth. It is generally interpreted as a sharp boundary representing the bottom of the asthenosphere, but not globally observed (Gu et al. 2001).

“410-km” discontinuity It is a globally observed jump over a narrow depth interval in seismic velocity, marking the transition from the $\alpha \rightarrow \beta$ phase of olivine near 400-km depth. This transition occurs at a temperature of about 1400–1450 °C.

“520-km” discontinuity Predicted by the phase diagram for olivine, which transforms to the γ phase under certain temperature conditions, this gradient in seismic velocities is occasionally observed.

Reflections or refractions from other depths have been observed – such as the “Hales discontinuity” within the lithosphere – and are occasionally attributed to a global physical or chemical transition, but a lack of consistency between such observations makes it more likely that the observations should be explained as wave energy returned from three-dimensional structure rather than from a discontinuity that represents an omnipresent layering.

Early regionalized refraction studies of the upper mantle already showed a marked variability in P and S velocity with depth. Surface wave studies, which are the preferred tool to investigate layers of low velocity, indicate minimum S velocities as low as 4.05 km/s under the Western United States, 4.09 km/s under the East African Rift, and 4.14 km/s under the Pacific Ocean, but body waves show a minimum S velocity as high as 4.63 km/s under the North American craton.

The Lehmann discontinuity is observed in few regional models, but it is present in the Preliminary Reference Earth Model (PREM) (Dziewonski and Anderson 1981), which shows a major velocity increase in P velocity of 7.1% at 220 km. By way of compensation, PREM has only a minor increase of 2.6% from 8.90 to 9.13 km/s at the “410-km” discontinuity. This, however, disagrees with all regional observations and reveals a major shortcoming of the reference model PREM. In fact, the variability in the velocity jump at 410 km is not very pronounced in the early refraction models. Typically, the P velocity in such models jumps about 5%. An average over seven regional models gives a P velocity jump from 8.78 ± 0.06 km/s to 9.26 ± 0.03 km/s, where the uncertainty represents one standard deviation. The jump in P velocity at 660 km over the same set of models is roughly 4% but more variable than that at 410 km: from 10.22 ± 0.20 to 10.72 ± 0.10 km/s. Near 660-km depth model PREM is in agreement with regional studies.

Though the regional models based on refracted waves provide the most accurate estimates of *absolute* velocities, the velocity–depth relationships represent horizontal averages

over thousands of km. We know that velocity variations exist over length scales much smaller than that. New tomographic techniques are able to delineate such variations and allow us to image them.

Tomographic Techniques

Knowledge of the three-dimensional upper mantle structure comes from tomographic techniques, notably:

- Transmission tomography of body wave delay times for both P and S velocity structure.
- Phase or group delay tomography using surface waves, primarily sensitive to S velocity.
- Imaging of waves reflected or converted at discontinuities (“receiver functions”), sensitive to the depth location of such discontinuities.
- Waveform modelling is able to combine the information of the previous three wave types in one inversion, though at the expense of very large computation times.
- Inversion of the splitting of normal mode frequencies by lateral heterogeneity, for long wavelength heterogeneity in both P and S velocity.

For an extensive overview of transmission tomographic techniques, see ► [“Seismic Tomography”](#). Each of these techniques has seen important progress in recent times. Ray theory is being replaced with first-order scattering theory that allows for the modelling of the frequency-dependent dispersion in delay times (Sigloch et al. 2008) or in receiver functions (Deng and Zhou 2015). Single station (or “single channel”) stacking of converted or reflected phases is being replaced by multichannel techniques, in particular Kirchhoff-type stacking along diffraction hyperboles much as one does to migrate seismic sections in exploration seismics (see Bostock 2009).

Seismic tomography allows the mapping of “anomalies” or deviations from a regular layering of the upper mantle. The most remarkable anomalies are listed here:

Subduction zones and the associated low velocity structure in the mantle wedge can be very clearly imaged because of increased seismicity when actively subducting. The observed velocity anomalies are consistent with average (cold) temperature anomalies of several hundred degrees.

Oceanic ridges are mapped best with surface waves, which leaves the exact depth extent as well as the temperature anomaly somewhat uncertain.

Cratonic roots were originally detected through the large negative delay times they cause for S waves, consistent

with a cold lithosphere (as much as 400° colder than oceanic lithosphere), but the depth extent is mapped using teleseismic surface waves. In the tectosphere model of Jordan (1981), the high density induced by the cooling is compensated by a chemical composition that is depleted in basaltic components.

Upper mantle plumes are rather narrow anomalies in the upper mantle but can be imaged adequately using body wave delays as well as surface wave observations from field deployments of portable seismographs. The velocity anomalies are consistent with temperature anomalies of 100–300 °C inferred from petrological studies.

Topography of the “410”- and “660”-km discontinuity is globally imaged using underside reflections of waves such as SS. This involves some geographic averaging, but topographic anomalies of 20 km or more are observed.

These anomalies are all visible in the variations of isotropic velocity variations. There is strong evidence, notably from the birefringence of SKS waves, that the seismic velocity in the shallow part of the upper mantle depends locally on the propagation direction of the wave; under favorable circumstances, this could in principle allow the mapping of mantle flow, since the crystal structure is assumed to align itself to the flow direction. However, at present there is little agreement between different tomographic models of anisotropy, partly because the SKS information is insensitive to depth, while the crustal correction, which is badly known, is in itself as large as the signal from anisotropy in surface waves (Ferreira et al. 2010).

Global Models

Schaeffer and Lebedev (2013) developed a detailed tomographic model of shear velocity variations in the upper mantle and compare this with five other models. At a length scale of thousands of km, all models are in agreement, but large differences still exist at shorter scales (500–1000 km). Very low velocities beneath oceanic ridges extend to about 100-km depth. The roots beneath the old cratons do not seem to extend far beyond 200-km depth.

Hosseini et al. (2018) collect 36 global models, not all independent. Figure 1 shows the upper mantle P-wave perturbations averaged over 12 of these models. Figure 2 shows the average S-wave perturbations averaged over 17 models. The ability to resolve depth is superior for S-wave models since these are partly based on surface wave information.

The averages displayed in Figs. 1 and 2 illustrate the global features that are present in all tomographic models: old continental shields (Canada, Scandinavia, Western

Earth's Structure, Upper Mantle, Fig. 1 An average over 12 tomographic models of P-wave velocity perturbations, plotted at 4 different depths in the upper mantle using the web-based toolbox of Hosseini et al. (2018)

Australia, West and South Africa) are characterized by high P and S velocities down to depths of about 250 km. The ridge in the North Atlantic interacts with the Iceland mantle plume and is still clearly visible at 250-km depth that shows low P and S anomalies. The oceans are generally characterized by low velocities throughout much of the upper mantle, with the exception of the South Atlantic and the western-most Pacific. Plume-like anomalies, with a high degree of vertical continuity in the upper mantle, are visible in the P velocity model beneath Hawaii, the Society Islands (Tahiti), and the East-African rift area (Afar). For a proper imaging of plumes, tomographic techniques that correct for the effects of diffraction around small or narrow anomalies are more suitable. Figure 3 shows models PRI-05 for P and S velocity in the upper mantle from Montelli et al. (2006), which clearly show a number of narrow upper mantle plumes.

Underside reflections from the upper mantle discontinuities allow the depth variations to the “410-” and “660-km” discontinuity to be mapped globally. This has most recently been done by Houser et al. (2008) using precursors to SS waves (Fig. 4).

Regional Models

Regional studies are able to offer a better resolution than the global efforts, certainly when using data from large and dense seismic arrays such as Skippy (Australia), USArray (USA), or HiNet (Japan), and other, usually temporary, deployments of broadband seismographs. Efforts to image the upper mantle beneath them have led to very precise images of subduction zone structure in particular. Figure 5 shows the slab subducting in the Fiji–Tonga region.

Though this slab image is continuous down to 600-km depth, slab geometry in the upper mantle is very variable, whereas some slabs remain for at least some time lodged in the transition zone others have no trouble sinking through the phase transition barrier at 660-km depth, with a negative Clapeyron slope and an increase of as much as two orders of magnitude in viscosity (Fukao et al. 2001).

A very different fate of subducting slabs is shown for the now inactive Farallon subduction beneath western North America, where the former Farallon plate is slowly disintegrating, letting mantle rock flow through major ruptures such as the “slab gap” in Fig. 6 (Sigloch et al. 2008).

Earth's Structure, Upper Mantle, Fig. 2 An average over 17 tomographic models of S-wave velocity perturbations, plotted at 6 different depths in the upper mantle using the web-based toolbox of Hosseini et al. (2018)

Outlook

It is now clear that the simple, layered models of the upper mantle are inadequate to explain many of the dynamic processes we observe at the Earth's surface. The resolving power of tomographic techniques is still growing because of theoretical improvements and the densification of seismic networks. The coming decades will undoubtedly reduce the high degree of nonuniqueness that still plagues tomographic images and allows for more reliable estimates of temperature and anisotropy. Floating seismic robots (see ► [“Floating Seismographs \(MERMAIDS\)”](#)) are opening up the oceans for dense seismic observations.

Luminous phenomena associated with earthquakes

Definition

Earthquake lights (EQLs) are anomalous luminosities associated with and presumably caused by the accumulation of stress, most characteristically before or during a seismic event or during an aftershock sequence. There is some disagreement over whether the term “earthquake lights” should also be applied to similar luminous phenomena observed in earthquake-prone areas or along faults without immediately associated seismic activity. In these cases the EQLs may be due to locally high stress levels in the Earth's crust that wax and wane without catastrophic rock failure or by earthquakes which are too distant or late relative to the observed EQL.

Classification of Earthquake Lights

The earliest known report of earthquake lights dates to at least 373 BCE when the Greek cities Helice and Buris were destroyed by an earthquake accompanied by “immense

columns of fire” (Seneca). Ancient references will always be questionable, especially when the surviving accounts are written later, but such references indicate that the people at that time were aware that lights might accompany earthquakes. Many sightings from various countries around the world have since been reported. They have been summarized in a number of papers (see, e.g., Thériault et al. 2014; St-Laurent et al. 2006; Derr 1973). As a result of extensive observations associated with the Saguenay earthquake sequence from November 1988 to January 1989, St-Laurent (2000) examined and extended earlier EQL classifications (e.g. Montandon 1948). Six types of luminous phenomena were documented:

1. “Seismic lightning” may appear to be similar to ordinary lightning. The latter appears to be an almost instantaneous flash lasting typically 30 μ s, but seismic lightning is an electric discharge lasting typically 150 ms, bursting out of the ground, rising upward into the atmosphere, and illuminating large areas of the sky without thunder. “Seismic lightning” can be mistaken for “sheet” or “heat” lightning at night which is too distant for thunder to be heard.
2. Luminous bands in the atmosphere at indeterminate height, sometimes horizontally or vertically and sometimes in a bundle, similar in appearance to some polar aurorae although, at much lower altitude, possibly even extending from the ground level upward.
3. Globular incandescences (moving or static), sometimes attached to luminous bands, called “orbs,” “globes,” or “meteors.” They have the appearance of ball lightning, e.g., of luminous spheres floating in midair, sometimes coalescing, lasting for up to a few minutes.

4. Fire tongues, small “flames” flickering or creeping along or near the ground, or like ignis fatuus.
5. Seismic “flames” seen emerging from the ground like an evanescent gas flame but very rarely causing visible burns.
6. Coronal and point-discharge-like lights.

A possible seventh type might be “luminous clouds” like those filmed shortly before the M 7.9 Wenchuan, China, earthquake of 12 May 2008 (YouTube 2008). These are phenomena in the high atmosphere, similar to “fire rainbows,” possibly linked to processes at the upper edge of the atmosphere and/or to ionospheric perturbations.

Examples of EQL

While reliable pictures of EQL are scarce, one example of type 1 comes from the Matsushiro earthquake swarm from 1965 to 1967, Fig. 1 (Yasui 1968, 1971; discussed in Derr 1973). Video of type 1 can be found in Heraud and Lira (2011). An example of type 3 was photographed at Tagish Lake, Yukon Territory, Canada, Fig. 2 (Jasek 1998), around 1 July, probably 1972 or 1973. While it is not possible to say that this picture is definitely EQL, these orbs are typical of the most-frequently observed EQL, as described by Montandon (1948). The only known photo of “flames,” type 5, was taken during the aftershock sequence to the Vrancea, Romania, earthquake of 4 March 1977, discussed in St-Laurent (2000). A sketch of type 6 comes from the account by Joseph A. Dallaire during the Saguenay M 5.9 mainshock of

Earthquake Lights,

Earthquake Lights,

Fig. 2 Earthquake lights from Tagish Lake, Yukon-Alaska border region, around 1 July, probably 1972 or 1973 (exact date unknown). Estimated size: 1 m diameter. Closest orbs slowly drifted up the mountain to join the more distant ones (Jasek 1998). (Photo credit: Jim Conacher, used with permission)

Earthquake Lights, Fig. 3 Drawing by artist from witness' description of a bright, fast-moving bluish-white light, preceded and accompanied by crackling noise emitted by the trees. Laterrière, Québec, 19 km N

of the epicenter, observed a few seconds before the M 5.9 mainshock of 25 November 1988. Not to scale (St-Laurent 2000). (© Seismological Society of America)

25 November 1988, Fig. 3 (presented in St-Laurent 2000). These examples are notable for the differences they exhibit: illumination of a broad area of the sky, discrete glowing plasmas, evanescent “flames,” and an electric discharge bursting through the surface of the Earth. They are representative of a number of other sightings, although the last one, the rapidly moving electric discharge, is so far unique in the detail of its description.

Example of Type 3 EQL

Schmidt and Mack (1912; Translation by Steven Soter, personal communication) give a number of eye-witness descriptions of type 3 EQL. The most detailed was by Friedrich Konzelmann, foreman in an Ebingen factory:

On the evening of 16 November [1911] between 10 and 10:30, I went home with my wife. My house is about 200 m from the city

Earthquake Lights, Fig. 4 Earthquake lights over Ebingen, Germany, 16 November 1911, ~10 pm. Observed and drawn by Friedrich Konzelmann (Schmidt and Mack 1912)

on the national road to Strasbourg. As we were about 30 m from our house, I heard a distant noise like thunder from Sigmaringen, followed by a faint vibration. As I glanced in the direction from which the noise came, I suddenly noticed at some distance a bright flash from the ground, which then at a considerable height turned into a ball of light, about the size of 20 suns. This ball maintained its brightness about 2–3 seconds and then divided itself like lightning in the direction of Ebingen. In my opinion the earthquake came from southeast to northwest. The earthquake began with the lighting of the fireball. After the rolling went past, I looked backward to the city and saw above the Katzenbuckel a similar but somewhat smaller fireball. The whole surroundings were brightly illuminated. (Fig. 4)

Source of EQL and Associated Electromagnetic (EM) Phenomena

The leading theory of how these various light phenomena are generated, based on extensive laboratory experiments, attributes them to effects by mobile positive hole charge carriers, which become activated when rocks are subjected to high levels of stress (Freund 2002, 2010, 2019). Positive holes exist in common rocks in a dormant state as peroxy links, $\text{O}_3\text{Si}^{\text{O}\cdot}\text{SiO}_3$, many of which are located at grain boundaries or may straddle grain boundaries. When stresses are applied, grains are moving relative to each other causing the peroxy links to break. They thereby activate electrons and positive holes, which immediately begin to recombine, returning to the inactive peroxy state. The difference between the rate of activation and rate of recombination determines how many of the positive hole charge carriers are able to flow out of the stressed rock volume into

the surrounding less stressed or unstressed rocks at speeds up to about 100 m/s (360 km/h or 220 miles per hour). Those positive holes constitute an electric current with attendant magnetic field variations and electromagnetic (EM) emissions. As positive holes arrive at the Earth surface, they create electric microfields powerful enough to field-ionize air molecules and to produce positive airborne ions, corona discharges, and EQL. They also recombine at the surface, returning to the peroxy state and leading to a distinct IR emission, spectroscopically identified in laboratory experiments and known from satellite infrared images as thermal infrared (TIR) anomalies.

How many peroxy a given rock contains represents an important factor. Gabbro and diabase often form vertical sheets of magmatic rocks called dykes, which have deep roots in the Earth's crust, even the upper mantle. They are emplaced during periods of extensional tectonics and are believed to be particularly rich in peroxy. When such rocks are stressed very rapidly, within milliseconds, for instance, by the passage of an earthquake wave, the number density of activated positive holes can instantly reach such high values that the electrical properties of the rocks change dramatically and outburst of electric charges can occur at the speed of light (Freund 2019).

The positive hole theory accounts not only for EQL but also for other pre-earthquake phenomena such as:

1. Air ionization at the ground-to-air interface with either exclusively positive airborne ions or corona discharges producing positive plus negative ions that tend to rise through the atmosphere. They are suspected to be linked

- to widely reported anomalous pre-earthquake fog/haze/cloud formation.
- Changes in the electrical conductivity of the soil and geoelectric potentials, both as a function of lateral distances and as a function of depth.
 - Geomagnetic anomalies in the Earth's crust due to stress-activated telluric currents that flow through the rock column.
 - Ionospheric perturbations in response to air ionization processes in the low atmosphere and/or low to ultralow electromagnetic emission from the Earth.
 - Ultralow and extremely low-frequency (ULF/ELF) and radio-frequency (RF) emissions. Such signals are being used successfully to forecast earthquakes 2–3 weeks in advance in the Peru subduction zone (Heraud and Lira 2011; Heraud et al. 2017).
 - Anomalous thermal infrared (TIR) emissions from around future epicentral areas, occurring particularly from topographic highs.
 - Unusual animal behavior thought to be triggered by air ionization at the ground-to-air interface, in particular by the formation of positive airborne ions or by broadband ultralow frequency (ULF) electromagnetic (EM) emissions from within the Earth's crust, due to stress-activated fluctuating telluric currents, which interfere with physiologically important EM emissions from living organisms such as the alpha brain waves (Freund and Stolz 2013).

Conclusion

At present there is no consensus among seismologists on the phenomenology and physical mechanism of EQL and associated EM phenomena. However, if the positive hole theory is correct, the entire suite of pre-earthquake phenomena, including EQL, may become useful in recognizing the build-up of tectonic stresses in the Earth's crust and, hence, for forecasting earthquakes.

Definitions and Introduction

Earthquake (EQ hereafter) prediction or forecast is to specify the source location, magnitude M , and occurrence time of EQ with certain accuracy before its occurrence. The terms prediction and forecast are often used with different nuances, the latter allowing for more stochastic nature. We will mainly use the former term in this entry. EQ prediction is often roughly classified by the length of concerned time into long term

($10^{1.5}$ – 10^1 years), intermediate term (10^1 – $10^{0.5}$ years), and short term ($<10^{0.5}$ year). EQ precursors are anomalous phenomena, which take place before EQs so that prediction is made on their information. This entry will focus on the precursors for short-term prediction. At this stage, however, the existence itself of the precursors has to be firmly established as a scientific fact, and further details of them must be thoroughly investigated.

Various EQ precursors have been noticed throughout human history until present day (Tributsch 1982). They are mostly short-term precursors on animals, plants, clouds, and sounds (see ► [“Earthquake Sounds”](#)). Precursors perceived without aid of scientific instruments are called macroscopic anomalies.

Precursors instrumentally recorded are classified into long-/intermediate- and short-term ones. Long-/intermediate-term precursors are active faults serve as geological precursors. Trenching of active seismic faults provides the dates and displacements of past large EQs, from which those of the next large EQ may be inferred. Other long-/intermediate-term precursors include the following:

1. Geodetic: land deformation, changes in sea-level, tilt, and strain
2. Seismological: seismic gaps (see ► [“Characteristic Earthquakes and Seismic Gaps”](#)), quiescence (see ► [“Seismic Quiescence and Activation”](#)), S wave splitting (see ► [“Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting”](#)), changes in micro-seismicity, seismic wave velocity, *b*-values, and characteristic EQs (see ► [“Characteristic Earthquakes and Seismic Gaps”](#))
3. Changes in electrical resistivity
4. Geochemical/hydrological: changes in radon, CO₂, and other gas discharge (see ► [“Isostasy, Thermal”](#)) and level and temperature of underground water (see ► [“Seismic Signals in Well Water Observations”](#))

Some, in particular, those in (3) and (4) serve for short-term EQ prediction also.

Short-term precursors which are of major concern of this article are mainly geochemical/hydrological and electric, magnetic, and electromagnetic (EM). The latter are changes in (1) geoelectric field (telluric current), geomagnetic field, and EM emissions at various frequencies (DC to VLF), (2) transmission properties of man-made EM waves of VLF to VHF range, (3) ionosphere (foF2 and total electron contents (TEC)), and (4) infrared (IR) or ground temperature. These changes are measured by apparatus on the ground or those mounted on artificial satellite.

Note that precursors and triggering effects are sometimes very difficult to discriminate. If the crustal state is very critical, small disturbances such as a passage of low atmospheric

pressures such as typhoons/cyclones/hurricanes may trigger earthquakes (e.g., Liu et al. 2009). The notable triggering effect is a large dam construction (see ► [“Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India”](#)). The case of Koyna dam in India is the most well-studied case (Gupta et al. 2011). Furthermore, water injection to deep well triggers earthquakes. Nowadays, shale gas retrieving is creating many induced earthquakes (e.g., Lei et al. 2017).

History

Zechariah of Israel (ca. 520 BC) is said to have issued the first long-term EQ forecast, based on the surface rupture of an EQ in 759 BC. Precursors were recorded as early as in 373 BC in Greece. Many followed from many parts of the world in the form of documents and folklore. In later years, even a larger number of macro-anomalies are kept accumulated (Tributsch 1982), now including such items as radio and TV noise, e.g., at 1995 M7.3 Kobe, 1999 M7.4 Izmit, and 1999 M7.7 Chichi EQs (Ikeya 2004). Most of macro-anomalies, however, have not been well studied systematically, although they apparently played significant roles, e.g., in the success of 1975 M7.3 Haicheng EQ prediction (Raleigh et al. 1977).

After 1906 M8.3 San Francisco EQ, through investigation of geodetic data on faults, the elastic rebound theory (see ► [“Earthquakes and Crustal Deformation”](#)) was developed, laying the theoretical foundation for EQ prediction. From the 1960s to the 1970s, countries including USSR, Japan, China, and the USA embarked on national scale EQ prediction projects. Projects consisted mainly of statistical approach for long-/intermediate-term prediction (see ► [“Statistical Seismology”](#)), but there was also deterministic approach to short-term prediction. In the early 1970s, the dilatancy-diffusion model (Sholtz et al. 1973) appeared. This model took advantage of results of field and laboratory studies obtained in various countries, like 10–20% Vp/Vs change in Garm, USSR (Semyenov 1969), and the USA (Aggarwal et al. 1973), crustal uplift in Japan (Danbara 1981), radon emission and electrical resistivity (Sadovsky et al. 1972), and so forth. All the quoted precursors, long and short, appeared to support the physical picture of the dilatancy-diffusion model. The famous prediction of 1975 M7.3 Haisheng EQ also was based on all kinds of precursors (Raleigh et al. 1977). Intermediate-term measures were taken in June 1974 and short-term in December 1974. Emergency alert to the public was issued in the early afternoon of February 4, 1975, several hours before the main shock to evacuate the public in time. These and other encouraging works in the 1960–1970s made the whole prediction community highly optimistic (e.g., Press 1975).

However, the period of optimism did not last long. First, later studies using controlled sources (McEvilly and Johnson 1974) did not confirm the significant change of V_p/V_s , which was the most critical background of the dilatancy-diffusion model. Second, for 1975 M7.8 Tangshan EQ, no timely alert was issued because there was no foreshock activity (see ► “Earthquake, Foreshocks”), despite many other precursors, causing the loss of many 100,000 lives (Chen et al. 1988).

In fact, the traditional seismological/geodetic methods were unable to short-term predict any great EQs (see ► “Great Earthquakes”) other than the Haisheng EQ. For none of these EQs, any pre-slip, the most legitimate short-term precursor from seismological point of view (e.g., Shibazaki and Matsu’ura (1995) and Kato and Hirasawa (1999)) has ever been detected. Yet, the main strategy of Japan Meteorological Agency (JMA) for short-term prediction of the Tokai EQ is to catch pre-slips as reported for 1944 M7.9 Tonankai EQ (Fig. 1; Mogi 1985). The Tokai EQ has been at a forecasted status since the late 1970s (Ishibashi 1981). Another well-publicized unsuccessful case is the Parkfield, where M6 class event was predicted in 1985 to come within 5 years, and 72 hours alert was issued in 1992 (Roeloffs 1994). It did not come until 2004, 12 years later (Bakun et al. 2005).

As a matter of fact, seismological precursors and methods, such as seismic gap (see ► “Characteristic Earthquakes and Seismic Gaps”), M8 algorithm (see ► “Earthquake Prediction, M8 Algorithm”), ZMAP (Wiemer and Wyss 1994), hotspots (Holliday et al. 2006), etc., were not aiming at short-term prediction. The new development and discoveries

in seismology such as the asperity models (Yamanaka and Kikuchi 2004), slow/silent EQs (see ► “Slow Earthquake”), and low-frequency non-volcanic tremors (Obara 2002) greatly contributed to the understanding of EQ mechanisms, but their direct relevance to short-term prediction has not been made clear. Characteristic EQ (see ► “Characteristic Earthquakes and Seismic Gaps”) may be the only case that can be quasi-short term predictable by seismic monitoring, but they are rare cases. By the late 1970s, general view of the main stream community became entirely pessimistic (e.g., Evernden 1982). This pessimism has persisted until now, making the word prediction almost “forbidden.”

It may be noted, however, that numerous undeniable short-term precursors were observed in non-seismic/geodetic (nonmechanical hereafter) fields. On top of many macro-anomalies, they were radon, CO_2 and other gas discharges, water level, and electric, magnetic, and EM anomalous changes.

Short-term EQ prediction may be realized only after the main stream strategy makes a change of course toward a nonmechanical approach, except for a few cases, e.g., GPS detected pre-seismic deformation from Kamchatka (Gordeev et al. 2001) and pre-seismic velocity changes at the Parkfield SAFOD drill site (Niu et al. 2008). However, thanks to the increase of the observation network and the progress of critical phenomena theory, even mechanical precursors recently began to be reported (e.g., Lippiello et al. 2012 (foreshock), Sarlis et al. 2015 (natural time analysis), Nanjo et al. 2012, 2016 (seismicity changes including b -value change), Tanaka 2012 (Tidal triggering)).

Earthquake Precursors and Prediction, Fig. 1 Precursory crustal deformation observed just before the M7.9 Tonankai EQ in 1944 (Mogi 1985)

Nonmechanical Short-Term Precursors

Difficulties Inherent to Short-Term Precursors

Short-term EQ prediction by standard mechanical approach seems to have scarce the chance except for clear foreshock activities because the instant the stress reaches critical state can hardly be pinpointed by the present seismic or geodetic observations. Nonmechanical precursors make use of some phenomena which necessarily occur at that instant as by-products of the same cause, the stress buildup. The only necessary condition to make them useful is that their critical stress is slightly smaller than that of EQ. When the state attains critical condition, EQ would occur soon after the detection of them, perhaps aided by the last push of some triggers.

There are two rates to evaluate precursors. One is success rate which is the number of successful predictions divided by the number of issued predictions, and the other is alarm rate which is the number of successfully predicted EQs divided by the number of target EQs. In applying these evaluating rates, criteria of success and failure, i.e., the allowable errors in the

three prediction targets, the dates, location, and magnitude, must be clearly stated. When they are presented properly, however, criticizing them as causal relation is not clear, or there are no other supporting geophysical simultaneous phenomena that seem unreasonable.

Macro-anomalies

Macro-anomalies are numerous, and the well-known examples, after the Haisheng EQ, are 1995 M7.3 Kobe, 1999 M7.4 Izmit, 1999 M7.7 Chichi EQs (Ikeya 2004), and 2008 M8.0 Shuchuan EQ (Fig. 2; Li et al. 2009). The causes of modern macro-anomaly precursors, such as radio and TV noise and malfunctioning of electrical appliances, are most probably related to pre-seismic EM emissions. Recently, Martilelli (2018) documented that earthquake precursors existed even in BC.

Geochemical/Hydrological Precursors

Geochemical/hydrological precursors are also diverse. Examples are discharges of radon, carbon dioxide, helium, H₂, and CH₄ (see Toutain and Baurbron 1999). Among them, radon

Earthquake Precursors and Prediction, Fig. 2 Abnormal animal behavior observed just before the M8.0 Wenchuan EQ in 2008 (Li et al. 2009). (a) Under free-running conditions, mouse locomotor activity presents circadian rhythm from B18 (18 days before EQ) to B04 (4 days before) and no rhythm from B03 (3 days before EQ) to A02

(2 days after EQ) including the day of EQ. Horizontal axis is 48 h (2 days). Diagonal solid lines mean the circadian rhythm does not coincide with 24 h. (b) The percentage of mice showing RLA (circadian rhythm of mouse locomotor activity) among the eight mice, indicating that some mice lost RLA around the EQ

emission has been most widely monitored, e.g., 1976 M7.1 Gazli EQ, Uzbekistan, 1985 M8.1 Mexico EQ, and 1995 M7.2 Kobe EQ shown in Fig. 3 (Yasuoka et al. 2009). Level changes of underground water are also potential precursors (e.g., Wang 1985 for Tangshan EQ, Igarashi et al. 1992 for 1992 M5.9 Tokyo Bay EQ.). Geochemical/hydrological precursors are often observed at localities long distance (100 km or more) away from epicenters. Perhaps their appearances are heavily controlled by local geological situations such as faults and poroelastic conditions (see ► “Seismicity, Intraplate”). For water level and temperature, coseismic changes are much more eminent and commonly observed than pre-seismic ones, in contrast to EM precursors (see later). In March 2011, the 2011 M9.0 off the Pacific coast of the Tohoku earthquake took place. This EQ brought us huge tsunami damage and severe nuclear power plant accident. This earthquake accompanied many precursors (Nagao

Earthquake Precursors and Prediction, Fig. 3 Time series of the daily radon concentration observed from January 1984 to February 1996. The daily minimum variation is shown by a black line and the normal variation by a gray line (Yasuoka et al. 2009). Clear enhancement of radon concentration can be seen before the M7.3 Kobe EQ

et al. 2014). Orihara et al. (2014) reported precursory water level change, which reached about 10 m for 2000 m deep well, about 3 months before the main shock. Furthermore, Tsunomori and Tanaka (2014) reported very large groundwater radon concentrations in Izu Peninsula. This change was the first for over 35 years of observation (Fig. 4). This well had been operated for Japanese EQ prediction research because of the well-recorded textbook-type radon change at the time of 1978 Izu-Oshima-Kinkai EQ (Wakita et al. 1980).

Satellite IR Images as Possible Surface Temperature

Anomalous satellite IR images as possible ground surface temperature have been reported over seismic regions (see ► “Isostasy, Thermal”). The meaning of satellite-observed IR anomalies, however, is not clear. There have been arguments on what they are and how they are formed. An alternative interpretation is that the satellite-observed IR image is not a temperature anomaly. When the p-holes (see later) arrive at the earth’s surface, they recombine to cause a spectroscopically distinct nonthermal IR emission (Freund 2009). Ouzounov et al. (2011) examined outgoing longwave radiation (OLR, infrared 10–13 μm) measured around troposphere before the 2011 Tohoku EQ. They claim that during 21–24 February and 7–10 March, transient OLR anomalous fields were observed near the epicentral area and over the major faults, with a confident level greater than 2 sigma.

Electric, Magnetic, and EM Precursors

Systematic research on EQ-related electric, magnetic, and EM phenomena was initiated more or less simultaneously in varied parts of the world in the 1980s. This relatively new branch of science is now called Seismo-Electromagnetics.

Telluric Current Precursors: The VAN Method

The VAN method, developed in Greece since the early 1980s, is named after initials of the founding scientists, P. Varotsos, K. Alexopoulos, and K. Nomikos (Varotsos and Alexopoulos 1984a, b). This has been the only working system for real short-term prediction for more than three decades. For $M \geq 5$ Greek EQs, the criteria for successful prediction imposed by

Earthquake Precursors and Prediction, Fig. 4 Radon concentration data from March 1977 to February 2012. A: onset time of 1978 Izu-Oshima-Kinkai EQ, B: onset time of 2011 Tohoku earthquake. (After Tsunomori and Tanaka 2014)

themselves are $<$ a few weeks in time, <0.7 units in M , and <100 km in epicentral location. SES (seismic electric signals) are transient DC geopotential variations observed before EQs by dipoles of buried electrodes at separate sites and continuously monitored at many stations (e.g., Varotsos 2005). By adoption of multiple dipole system, they accomplished successful noise rejection. Single SES precedes single EQ, whereas the so-called SES activity, which consists of a number of SES in a short time, is followed by a series of EQs.

VAN group made two major discoveries. One is the “Selectivity,” which means that only some sites are sensitive to SES, and a sensitive site is sensitive only to SES from some specific focal area(s). This information helps for estimating the epicenter area. The selectivity is considered to be originated from the inhomogeneity of the subterranean electrical structures, i.e., SES goes only through underground conductive channels to sensitive sites. The other is the “VAN-relation” which means that the focal distance r , EQ magnitude M , and the potential difference ΔV for dipole of length L are related by $\log(\Delta V/L \times r) = aM + b$ where a is a constant 0.34–0.37 and b is a site-dependent constant. Once the epicentral location is estimated from the selectivity

data, M can be assessed since both $\Delta V/L$ and r are known. The VAN method has been a contentious subject (e.g., Geller 1996; Lighthill 1996). However, it has well survived all the criticism.

In Japan, VAN-type monitoring has been tried since the late 1980s (Uyeda et al. 2000). Despite the high-level noise of DC trains, the existence of the VAN-type SES has been confirmed. In the year 2000, a 2-month long seismic swarm, with 7,000 $M \geq 3$ shocks and 5 $M \geq 6$ shocks, occurred in Izu Island region. For this swarm activity, significant pre-seismic electric disturbances were observed (Fig. 5, Uyeda et al. 2002).

Ultralow Frequency (ULF) Precursors

Well-known example is the case of the 1989 M7.1 Loma Prieta EQ (Fraser-Smith et al. 1990). The horizontal component measured at a site 7 km from the epicenter started anomalous enhancement about 2 weeks prior to and a sharp increase a few hours before the EQ. The disturbance lasted for about 3 months after the EQ. These have never been observed at any other time during the observation of more than 15 years. Reports of observing pre-seismic ULF geomagnetic anomalies have been made also for 1988 M6.9 Spitak

Earthquake Precursors and Prediction, Fig. 5 Anomalous geo-electric potential changes in ULF (0.01 Hz) band prior to 2000 seismic swarm activity in Izu island region, Japan. The bottom panel shows seismicity. (Modified from Uyeda et al. 2002)

(Armenia) EQ (Kopytenko et al. 1993) and 1993 M8.0 Guam (Marianas) EQ (Hayakawa et al. 1996). There are some discussions pointing out that these ULF signals might have been artifact or magnet-telluric origin (e.g., Thomas et al. 2009). Concerning ULF anomalies, some statistical works were made during last decade (e.g., Hattori et al. 2013; Han et al. 2014). Han et al. (2017) showed a correlation between the ultralow frequency (ULF) seismo-magnetic phenomena and local seismicity in the Kakioka region, Japan. They used Molchan's error diagram (see Molchan and Kagan 1992) for statistical evaluation. For instance, the results indicate that predictions based on ULF magnetic data in Kakioka, Japan, perform better than random prediction.

Higher-Frequency EM Emission

Gokhberg et al. (1982) was a pioneering observation of pre-seismic EM wave emission in the LF range. Asada and his group in Japan monitored the wave forms of two horizontal magnetic components of VLF EM waves, through which apparent incoming directions of VLF pulses were assessed (Asada et al. 2001). They found that, a few days before M5 class land EQs within 100 km of their stations, pulses with fixed incoming direction appeared and the EQ actually occurred in that direction, whereas the sources of overwhelmingly more numerous and stronger noises were moving along with lightning sources

Warwick et al. (1982) reported on the observation of high-frequency radio waves possibly related to the precursory activity of 1960 Great M9.5 Chilean EQ. This was probably the first report of this kind. Enomoto et al. (2006) recorded

two events of anomalous geo-electric current pulses (HF-band) at Erimo station, Hokkaido, Japan. One in 2000–2001 occurred before and during the volcanic activity of Mt. Usu (200 km away), and the second started 1 month before 2003 M8.0 Tokachi-Oki EQ (80 km away). These were the only anomalies during the 10-year observation period.

Lithosphere-Atmosphere-Ionosphere Coupling

Sub-ionospheric anomalies before large EQs were reported (e.g., Molchanov and Hayakawa 1998) through monitoring 10–20 kHz VLF ship-navigation waves, although Clilverd et al. (1999) did not obtain similar results. A decrease in electron density of ionosphere within 5 days before $M \geq 5$ class EQ was found in Taiwan by the ionosonde measurements of critical plasma frequency, foF2 (see Fig. 6; Liu et al. 2006). Fujiwara et al. (2004) found pre-seismic atmospheric anomalies causing FM radio transmission anomalies within 5 days before $M \geq 4.8$ EQs, which was pioneered by Kushida and Kushida (2002). Moriya et al. (2010) further promoted this study and obtained statistical relations between the total time length of anomalous reception and EQ magnitude. The concept of pre-seismic lithosphere-atmosphere-ionosphere coupling (LAI coupling) arisen from these investigations became an important issue in precursor studies (Pulinets and Boyarchuk 2005; Kamagowa 2006), because some causative factor should exist in the lithosphere, and there should be some mechanism to transport its energy to the high atmosphere.

Considering earthquake prediction research from space, the French satellite program was truly an epoch. The French

Statistical significance of pre-seismic ionospheric anomaly (PEIA) (after, Liu et al. 2006). (a) Cross-correlation coefficient between EQs and anomalies with time lag. The shaded area denotes the rejection bounds at significance level 0.01. (b) Odds of the shallow EQs with the PEIA against the magnitude and distance. Odds versus related mean magnitude (left), and odds versus related mean distance (right). The shaded areas in the two plots denote the rejection value of odds as 2.5 under significance level of 0.01

government launched the DEMETER (Detection of Electro-Magnetic Emissions Transmitted from Earthquake Regions) satellite in 2004 (see Parrot 2018). A lot of satellites measured many plasma parameters such as electron density, temperature, ULF-HF band electromagnetic waves, etc. As a result of the analysis, it was proposed that the most statistically significant precursor was a nighttime VLF electric field intensity decrease phenomenon that seems to be due to the D region fluctuation just before earthquakes (Fig. 7, Pisa et al. 2013).

As mentioned above, there are many reports that the ionosphere changed before earthquakes. Outstanding findings were reported in the 2011 Tohoku M9 earthquake. Total electron content (TEC) in the ionosphere relatively increased from 40 min before the main shock (Heki 2011). Although the pre-seismic TEC clearly increased, this phenomenon seemed an artifact change for Kamogawa and Kakinami (2013). In the very beginning, Heki claimed that “TEC increases,” but now the expression that “TEC curve” is “bent” just before the M8 class earthquake is used, and now Kamogawa agrees with this expression (Kamogawa, private communication). Now Heki and his colleagues confirmed that the same phenomenon occurred immediately before all eight earthquakes with a moment magnitude of 8.2 or larger. Note that there are many similar ionospheric changes without the earthquakes. Their further study supports this phenomenon using ionospheric three-dimensional tomography (e.g., He and Heki 2016) just before the huge earthquake. In addition, theoretical research for this phenomenon also comes to be very active (e.g., Kelley et al. 2017) (Fig. 8).

Possible Mechanism of Pre-seismic EM Emissions

It is often questioned why EM signals, such as SES, appear only pre-seismically and not coseismically. This point makes

Earthquake Precursors and Prediction, Fig. 7 Frequency-time dependence of the probabilistic intensity obtained from the nighttime electric field data measured within 440 km of the epicenters of earthquakes with magnitudes greater than >5.0 (Pisa et al. 2013)

scientific community dubious about EQ-related EM precursors in general because EQ is by far the most energetic event. Actually, coseismic signals are routinely observed, but they are not useful as precursors. Moreover, all the so-called coseismic EM signals observed so far were found to occur at the time of the arrival of seismic waves. They are, therefore, “coseismic wave” and not “true” coseismic. The fact that no true coseismic signals are observed may be an important clue in exploring the physical mechanism of generation of both EM signals and EQs themselves. In fact, the slow pre-seismic stress buildup and the instantaneous stress release at EQ are physically very different processes, and there is no compelling reason why they generate similar EM signals.

The generation mechanism is different for different frequencies. It may be the electrokinetic effects (e.g., Mizutani et al. 1976; Fitterman 1978) and/or pressure-stimulated current (PSC) effects for DC to low-frequency signals and piezoelectric effects and exo-electron emission (Enomoto and Hashimoto 1990) for higher-frequency signals. A mechanism involving the positive holes (p-holes) in rock forming minerals under stress has also been proposed.

The PSC was proposed by Varotsos and Alexopoulos (1986). The impurities and vacancies form randomly oriented local electric dipoles, which align their orientation in avalanche following an activation process to generate the electric current. PSC model is unique in generating currents during gradual stress buildup without requiring any sudden change of stress. Freund and his colleagues are proposing a different mechanism for ULF electric signals (Freund et al. 2006). They discovered in laboratory that when a block of igneous rock is put under stress locally, the rock turns into a battery without external electric field. The charge carriers in this case are semiconductor-type positive holes (p-holes) which is oxygen in one-valence state. They attribute the satellite image of pre-seismic IR anomalies to the result of recombination of two p-hole charge carriers at earth’s surface as mentioned earlier (e.g., Freund 2009; Takeuchi and Nagao 2013).

Although models related to micro-cracking based on laboratory experiments such as discharge of screening charge of piezoelectric polarization (Ikeya 2004; Yoshida et al. 1997), electrification of fresh crack surfaces (Yamada et al. 1989), and exo-electron have been proposed, there have been no reliable field reports on the occurrence of pre-main shock micro-cracking. Furthermore, it might be pointed out that in all these models much stronger coseismic signals would be expected.

Critical Phenomena

EQ may be a critical phenomenon defined in statistical physics (e.g., Bak and Tang 1989) which means that the short time EQ prediction is synonym for identifying the approach to criticality. Although this is difficult to achieve (see Main 1995), it has been recently shown that by analyzing time

Earthquake Precursors and Prediction, Fig. 8 The residual plot of VTEC for the eight earthquakes is compared. Mw is indicated within the parentheses. Red rectangles indicate the times of positive breaks. (After Heki and Enomoto 2015)

series of seismicity in a newly introduced time domain “natural time,” the approach to the state of criticality can be clearly identified (Sarlis et al. 2008). This way, they seem to have succeeded in shortening the lead time of VAN prediction to only a few days (Uyeda and Kamogawa 2008). We thought that seismic data can play an amazing role of short-term precursor when combined with SES data. However, with the recent progress of the critical theory, seismic data alone can play important role for the short-term prediction (e.g., Sarlis et al. 2013; Kamogawa et al. 2019).

Summary and Future Outlook

Most of the precursors mentioned above are possibilities, but so far they were recognized or documented only after main shocks, and they gave scarce constraints on the source location and magnitude M (except VAN’s SES). Much more enhanced research is needed to make them practically useful precursors.

1. Some macro-anomaly short-term precursors are real. Scientific research on them is inadequate so far.
2. Seismic and geodetic precursors can be useful for long/intermediate EQ prediction.
3. Foreschock activity may be useful for short-term prediction.
4. Nonmechanical precursors, such as some geochemical, hydrological, and EM precursors, are plausible for short-term EQ prediction. For sooner realization of practical short-term prediction, more research on them must be promoted.

²Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences (IEPT RAS), Moscow, Russia

Definition

An *earthquake* is a sudden movement within the Earth's crust or the upper mantle that releases tectonic stress and, usually, originates seismic waves. The hierarchy of movable lithospheric volumes composes a large nonlinear dynamical system. Prediction of such a system in a sense of extrapolation of trajectory into the future is futile. However, upon coarse-graining, the integral empirical regularities emerge opening possibilities of earthquake prediction (Keilis-Borok et al. 2001).

Earthquake prediction is a statement about future earthquake occurrence based on the information, data, and scientific methods that are available now. To predict an earthquake, someone “must specify the expected magnitude range, the geographical area within which it will occur, and the time interval within which it will happen with sufficient precision so that the ultimate success or failure of the prediction can readily be judged. Only by careful recording and analysis of failures as well as successes can the eventual success of the total effort be evaluated and future directions charted. Moreover, scientists should also assign a confidence level to each prediction” (National Research Council 1976).

Introduction

According to the definition of earthquake prediction, one can classify an earthquake prediction of certain magnitude range by duration of time interval and/or by territorial specificity. Four major stages can be distinguished in temporal earthquake predictions: (1) long-term, (2) intermediate-term, (3) short-term, and (4) immediate (see Table 1).

Long-term prediction is essentially based on the determination of probabilities of active fault segments to rupture for the next few decades (e.g., Working group on California earthquake probabilities 1999). This kind of prediction can guide engineering and emergency planning measures to mitigate the impact of a target earthquake.

An intermediate-term prediction for the next few years is an update of the long-term prediction by some indicators (e.g., an increase in background seismicity, clustering of events in

space and time, transformation of magnitude distribution, and some others). The M8 algorithm is designed for an intermediate-term prediction of earthquakes (Keilis-Borok and Kossobokov 1990).

In the 1980s, P. Varotsos, K. Alexopoulos, and K. Nomicos proposed the VAN method (named after the researchers' initials) of short-term earthquake prediction for the next few months/weeks, which is based on detection of characteristic changes in the geoelectric potential via a telemetric network of conductive metal rods inserted in the ground (Lighthill 1996).

Immediate earthquake prediction for the next few hours is sometimes mixed with "early warning," which is usually based on the first arrival of seismic waves and transmission of an electronic alert within a lead-time of seconds. Early warning is used (e.g., in Japan) to shut down gas and electricity grids and to stop high-speed trains in the event of a strong earthquake.

Following common perception, some investigators concentrate their efforts on predicting the "exact" fault segment to rupture, e.g., the Parkfield earthquake prediction experiment (Bakun and Lindh 1985), which is by far more difficult and might be an unsolvable problem (Main 1999). Being related to the rupture size L of the incipient earthquake, predictions could be summarized in a classification that distinguishes

several options of wider spatial ranges of certainty and not only "exact" mode of prediction (Table 1). The Gutenberg–Richter power law relation between the number of earthquakes and their magnitude suggests limiting magnitude range of prediction, $Mm + = [m, m + \Delta m]$, to about one unit or less (i.e., $\Delta m \leq 1$).

From a viewpoint of such a classification, the earthquake prediction problem might be approached by a hierarchical, step-by-step prediction technique, which accounts for multi-scale escalation of seismic activity to the main rupture (e.g., Keilis-Borok 1990; Kossobokov et al. 1999). It starts with term-less recognition of the earthquake-prone zones (Gorshkov et al. 2003) and then follows with determination of the areas of different spatial ranges, where long- and intermediate-term *times of increased probability* (TIP) of a target earthquake occurrence are estimated. Finally, a forecast may come out with short- or immediate-term alerts at specific sites.

The M8 Algorithm

The intermediate-term middle-range earthquake prediction method, called briefly the *M8 algorithm*, was designed by retroactive analysis of dynamics in seismicity preceding the great, magnitude 8.0+, earthquakes worldwide, hence its name. The exact definitions and computer code of the M8 algorithm can be found in Keilis-Borok and Kossobokov (1990), Healy et al. (1992), and Kossobokov (1997).

Prediction is aimed at the earthquakes of magnitude M , where $M \in [m_0, m_0 + \Delta m] = M_0 +$. The territory of the seismic region under study is analyzed by moving overlapping circles of the fixed size (by a factor of about 5–10 larger than a source size of target magnitude M_0 events) (Fig. 1). The sequence of earthquakes with aftershocks

Earthquake Prediction, M8 Algorithm, Table 1 Classification of earthquake predictions

Temporal, in years		Spatial, in source zone size L	
Long-term	10	Long-range	Up to $100 L$
Intermediate-term	1	Middle-range	$5\text{--}10 L$
Short-term	0.01–0.1	Narrow	$2\text{--}3 L$
Immediate	0.001	Exact	$1 L$

Spatial accuracy of predictions depends on the source size L of target earthquakes

Earthquake Prediction, M8 Algorithm, Fig. 1 General scheme of the M8 algorithm. *Left panel:* Circles of investigation overlay the targeted seismic region; seismic sequences in each circle give a description of seismic activity, which is then used to diagnose an alert (TIP). *Right panel:* presents the plots of the M8 algorithm's functions (explained below) with time. The interval of TIP is shaded by gray; the asterisk denotes the large event occurred; and the white dots show anomalously high values of the functions

removed is considered within each circle. Sequences in different circles are normalized to the annual number of earthquakes $\bar{N}$ by selecting the lower magnitude cutoff $\underline{M} = M_{\min}(\bar{N})$.

For this sequence, several functions are computed in the trailing time window $(t-s, t)$ and the magnitude range $(\underline{M} \leq \text{magnitude} < M_0)$. These functions include (1) the number of earthquakes $N(t)$ of magnitude M or greater; (2) the deviation of $N(t)$ from longer-term trend $L(t)$; (3) concentration $Z(t)$ estimated as the ratio of the average source diameter to the average distance between sources; and (4) the maximum number of aftershocks $B(t)$. Each of the functions N , L , and Z is calculated twice with $\underline{M} = M_{\min}(\bar{N})$ for $\bar{N} = 20$ and $\bar{N} = 10$. As a result, the earthquake sequence is given a robust averaged description by seven functions $N1$, $N2$, $L1$, $L2$, $Z1$, $Z2$, and B (Fig. 1). An alarm or a TIP is declared for 5 years when at least six out of seven functions, including B , become “anomalously large” within a time window of 3 years.

Retrospectively the M8 algorithm was applied to predict earthquakes from different magnitude ranges in a number of regions worldwide. Its modified versions targeting earthquakes from magnitude ranges down to M5.5+ were found efficient in regions of seismic activity lower than required by the original version (Kossobokov and Shebalin 2003; and references therein).

The MSc Algorithm

The second approximation prediction method, called briefly the *MSc algorithm* (Kossobokov et al. 1990), was designed by retroactive analysis of the detailed regional seismic catalog prior to the Eureka earthquake (1980, M7.2) near Cape Mendocino in California, hence its name, *Mendocino Scenario*, and an abbreviation. The MSc algorithm is applied to reduce the area of alarm by analyzing dynamics at lower magnitude levels of seismic hierarchy. Sometimes, the data is enough to get a near-perfect outline of the incipient large earthquake. More often, the catalog of earthquakes is just enough for the M8 analysis but insufficient for the MSc application.

Qualitatively, the MSc algorithm determines an area of the territory of alarm, where the activity recognized by the first approximation prediction algorithm (e.g., by the M8 algorithm) within a sufficient temporal and/or spatial span is continuously high and infrequently drops for a short time. The phenomenon, which is used in the MSc algorithm, might reflect the second (possibly, shorter-term and, definitely, narrow-range) stage of the premonitory rise of seismic activity near the incipient source of the main shock. The MSc algorithm reduces area of the M8 predictions much better (by at least a factor of 2) than a few simple alternatives like all earthquake-prone or the most active cells that contain

certain part of the recent seismic activity (Kossobokov et al. 1990). Fig. 2 shows, as an example of the M8-MSc forecast in the real time, the case history of June 4, 2000, M8.0 Sumatra earthquake.

The earthquake prediction algorithms M8 and MSc receive a fair amount of attention due to ongoing real-time experimental testing unprecedented in rigor and global coverage (Healy et al. 1992; Kossobokov et al. 1999). Relevant predictions are communicated, with due discretion, to several dozens of leading scientists and administrators in many countries. The accumulated statistics of this experiment confirm intermediate-term predictability of large earthquakes with middle- to exact-range of location (Kossobokov 2006). Table 2 summarizes the prediction outcomes for the great (magnitude 8.0+) earthquakes. For the last 34 years, 17 out of 27 great earthquakes were predicted by the M8 algorithm, while the M8-MSc algorithm narrows the area of alarm at the cost of additional six failures-to-predict. The ratio of the *space-time volume alerted by the algorithms* (i.e., alarms) to the total space-time volume is about 31% in the case of the M8 algorithm and 15% in the case of the M8-MSc algorithm. A confidence level estimate tells how sure one can be that the achieved performance of the algorithm is not arisen by chance. To bring the confidence level down to generally accepted value of 95%, the ongoing experimental testing has to encounter 11 failures-to-predict in a row for the M8 algorithm and 18 in the case of the M8-MSc narrow-range predictions, which appears absolutely unlikely to happen. The progress in hypocenter determination in the last decades resulted in a possibility of expanding the territory of testing the M8 and M8-MSc algorithms (Kossobokov 2017).

Earthquake Prediction, M8 Algorithm, Fig. 2 Prediction of June 4, 2000, M8.0 Sumatra earthquake. The main event and its aftershocks are marked by circles

Targeting Mega-earthquakes

The December 26, 2004, M9.2 Sumatra-Andaman (S-A), March 28, 2005, M8.5 Nias, February 27, 2010, M8.8 Chile, and March 11, 2011, M9.1 Tohoku mega-earthquakes, which ruptured the 1300-, 400-, 600-, and 500-km portions of subducting margins of the Indian and Pacific Oceans, are not included in Table 2 because of their rupture size. According to the M8 methodology, much larger circles of investigation (CI) with diameter of several thousand kilometers should then be employed to search for a precursory seismic activation in advance of mega-earthquakes. An application of the M8 algorithm targeting M9.0+ earthquakes could have predicted these earthquakes (see <http://www.mitp.ru>, section “Predictions”).

Actually, the retrospective application of the M8 algorithm (with the 6000-km diameter CI) showed that in July 2004 the precursory seismic activation was widespread over the most of the earthquake-prone areas of the Earth (Romashkova 2008). This activation reduced to four clusters of TIPs by 2008. The largest cluster includes S-A and adjacent major seismic zones from Kashmir in the North-West to Timor Islands in the East, where March 28, 2005, Nias, M8.7

mega-earthquake and coupled September 12, 2007, Southern Sumatra, M8.5 and M7.9 great earthquakes have already confirmed the M8 algorithm diagnosis (see <http://www.mitp.ru>; note that an access to the current predictions is available only for experts; contact volodya@mitp.ru for the access code). Two of the other three smaller clusters of TIPs, i.e., the circles centered at (31°S, 70°W) and (45°N, 150°E) got their confirmations with the occurrences of February 27, 2010, offshore Maule, Chile M8.8 and March 11, 2011, M9.1 Tohoku mega-earthquakes (Fig. 3).

Figure 3 does not show these CIs, but the TIPs in smaller (667-km diameter) CIs of the regular M8 algorithm diagnosis aimed at M8.0+. Evidently, this provides a narrow-range reduction of the prediction uncertainty acting as the second approximation to diagnosis aimed at M9.0 + .

Conclusion

High statistical significance of intermediate-term earthquake prediction methods, achieved in the ongoing experimental testing worldwide, confirms the following paradigms:

Earthquake Prediction, M8 Algorithm, Table 2 Worldwide performance of earthquake prediction algorithms M8 and M8-MSc

Test period	Large earthquakes						
	Predicted by		Total	Alarms, %		Confidence level, %	
	M8	M8-MSc		M8	M8-MSc	M8	M8-MSc
1985–2019	17	11	27	30.92	14.59	99.94	99.91

Earthquake Prediction, M8 Algorithm, Fig. 3 Global testing of the M8-MSc predictions in advance of February 27, 2010, M8.8 offshore Maule, Chile (a) and March 11, 2011, M9.1 Tohoku (b) mega-earthquakes. The epicenters of the main shock (big star) and its after-shocks (white dots) fill the portion of the subduction zone, which is about

one half of the major seismic segment recognized (gray outline) as capable of producing a magnitude M8.0+ event in the ongoing real-time experimental testing. March 9, 2011, Sankiru-Okii M7.3 foreshock of the Tohoku mega-earthquake is marked by a small dark gray star

(1) precursory seismicity patterns exist; (2) the dimension of an area where precursory seismicity pattern appear is by far (about ten times) larger than that of source zone of the incipient large earthquake; (3) many precursory seismicity patterns are similar in regions of different seismic and tectonic environment; and (4) some precursory seismicity patterns are universal. Their analogs take place in advance extreme catastrophic events in other complex nonlinear systems.

Our knowledge of earthquake physics and earthquake dynamics is not sufficient to predict strong earthquakes with a high accuracy. We do not know well (1) how earthquakes, especially large events, originate; (2) when an earthquake starts, when it stops, and what magnitude could it be; (3) how and why earthquakes cluster; and (4) what were the initial conditions of stress state before a large event in terms of stress transfer.

The scientific community should use the full potential of mathematics, statistics, statistical physics, and computational modeling and the data derived from seismological (monitoring of physical parameters of earthquakes and tectonic stress, fluid migration, etc.), geodetic (GPS, InSAR, and other measurements of the crustal deformation), and geological (e.g., determination of the time intervals between large earthquakes using paleo-seismological tools) studies to improve intermediate- and short-term earthquake predictions (Ismail-Zadeh 2010).

Though the current accuracy of earthquake prediction is limited, any scientifically validated prediction can be useful for earthquake preparedness and disaster management, if the accuracy of the prediction is known, even though it is not high. An inexpensive low-key response to intermediate-term middle-range predictions described here is well justified, if even a little part of the total damage due to a strong event is prevented.

Earthquake Rupture: The Inverse Problem

Shamita Das

Department of Earth Sciences, University of Oxford,
Oxford, UK

Definition

Forward problems are those in which given the cause we are required to find the effect. For example, in seismology, given the Earth structure, find the expected arrival times of different

seismic phases. Or, given the details of the earthquake rupture process, find the seismograms at different stations. Inverse problems are those in which we are given the effect and required to find the cause. For example, given the times of arrivals of, say, P-waves at different stations from an earthquake, find the hypocentral location. Or, given the travel time curves, find the Earth structure. In seismology, as in all branches of geophysics, it is inverse problems that we are most interested in, forward problems being very useful in elucidating the physical principles underlying the problem.

Forward problems	Inverse problems
Serve to elucidate underlying physical principles	Say, given some gravity anomaly, find shape and density of anomalous body
Solutions are unique	Solutions are non-unique, i.e., more than one density distribution can give same anomaly

Introduction

The inverse problem of earthquake source mechanics consists of analyzing seismograms to obtain detailed information on the earthquake rupturing process. In particular, some of the questions that seismologists are interested in are how does the motion develop over the fault area during the time period that the two sides of the fault are moving past one another, at what rupture speed does slip spread out over the fault, at what speed do the two sides of the fault slide past one another, and what is the resulting stress drop over the fault. Such information is essential for reliable seismic hazard assessment.

Definition of Some Common Terms Used in Inverse Theory

Stability is defined as the property that a solution is insensitive to small random errors in the data. Non-uniqueness is the property that more than one solution (almost) equally well-fitting the data exists. Robustness is the property that a solution is insensitive to a small number of large errors (“outliers”) in the data. As stated by Das and Kostrov (1990), from the computational point of view, this instability manifests itself as non-uniqueness of the solution, in numerical problems.

The solution of this problem is far from trivial, because it is unstable (Kostrov 1975; Kostrov and Das 1988), and from the computational point of view, this instability manifests itself as non-uniqueness of the solution, as mentioned above. Adding constraints to the solution of the relevant equations has been shown to stabilize the problem. Such constraints appear best when based on the physics of problem, that is, the physics of the earthquake faulting process. Unfortunately, our knowledge of the physics of the earthquake process is still limited.

So, seismologists have had to use those properties which are considered to be reliably known. For example, forward modeling showed that it is not likely that there is major back-slip on the fault. So, a constraint that is often used is the requirement is that the slip rate vector is positive, that is, no back-slip is permitted on the fault. While, in principle, slip in the opposite direction is possible due to interference of waves on the fault, especially at the fault edges, experience from three-dimensional forward modeling shows that such back-slip is likely to be very small. This constraint has been used by Olson and Apsel (1982), Hartzell and Heaton (1983), and Das and Kostrov (1990, 1994), among others, and has been shown to stabilize the solution. Other possible constraints, such as requiring the solution to be in agreement with the seismic moment obtained from the centroid moment tensor solution or from geodetic measurements, or, requiring the fault rupture speed to be limited by some wave velocity, can also be used. Further constraints such as requiring the maximum slip rate on the fault to be limited by some considerations from fracture mechanics could also be considered, though this has not yet been implemented in currently used methods. It has been found that minimizing the seismic moment often provides stable solutions. Laboratory experiments have recently played a crucial role in providing such constraints and will be discussed later.

As stated by Olson and Apsel (1982), in order for a particular rupture process to be an acceptable solution to the inverse problem, it must satisfy the following three conditions:

- 1. The solution must explain the data.
- 2. The solution must be physically reasonable (consistent with independent constraints).
- 3. If more than one solution fits the data equally well, additional information must be supplied to uniquely define which solution is being obtained.

The Method

The rupture process is solved for by determining the slip rate distribution over the fault in time, and the entire rupture process is reconstructed from it. For example, the final slip distribution is found by integrating the slip rate distribution over time. The rupture speed can be found by tracking the rupture front and so on. It should be noted that fault slip rate and fault rupture speed are very different quantities and should not be confused. Faults slip at rates of about m/s, whereas the rupture speed is generally about 90% or more, of the shear wave speed of the medium in which the fault is propagating, that is about 3 km/s or more.

To invert for the three-dimensional slip rate distribution (two spatial dimensions on the fault and time) is a computationally difficult task. Not surprisingly, simplified methods of

E

solving the problem have been used. For example, in order to reduce the number of unknowns, one often restricts for how long a point on the fault can slip. But, in reality, if some region of the fault re-slips, or has delayed slip, both shown to be feasible in forward models, this may not be found by the solution. This restriction would inhibit discovering fault complexity. The discretization itself may implicitly impose some constraint on the solution. It is thus important to ensure that the solution methods do not impose any implicit (and unknown) constraints on the solution, and if such constraints are unavoidable, they must be kept in mind when interpreting such solutions in geophysical terms.

To formulate the problem, we start from the representation theorem (e.g., Aki and Richards 1980), where the ground displacement at a station located at a point $\mathbf{x}$ on the Earth's surface can be expressed in terms of the slip distribution over a fault Σ as

$$u_k(\mathbf{x}_1, t_1) = \int_0^{t_1} dt \iint_{\Sigma} K_{ik}(\mathbf{x}_1, \mathbf{x}, t_1, t) a_i(\mathbf{x}, t) dS \quad (1)$$

where $i, k = 1, 2, 3$, $u_k(\mathbf{x}_1, t_1)$ are the components of the displacement vector, $a_i(x, t)$ are the components of the slip, and $K_{ik}(\mathbf{x}_1, \mathbf{x}, t_1, t)$ are the components of the impulse response of the medium at $(\mathbf{x}_1, t_1)$, due to a dislocation point source at $(\mathbf{x}, t)$. Assuming a planar fault and the slip direction on the fault to be constant, we can write, after some transformations:

$$S_j(t_1) = \int_0^{t_1} dt \iint_{\Sigma} W_j(\boldsymbol{\xi}, t_1 - t) \dot{a}(\boldsymbol{\xi}, t) dS \quad (2)$$

where j identifies the station and ground displacement components of the seismogram $S(t_1)$, $W_j(\boldsymbol{\xi}, t)$ is the impulse response at $(\boldsymbol{\xi}, t)$ corresponding to a fixed slip direction, $\dot{a}(\boldsymbol{\xi}, t)$ is the fault slip rate, the two-dimensional vector $\boldsymbol{\xi}$ gives the position on the fault relative to some reference point (e.g., the earthquake hypocenter), and t is the time measured from the origin time of the earthquake. With a continuous distribution of stations, Eq. (2) would represent an integral equation of the first kind (and such equations are known to be unstable).

The following additional constraints are often used:

$$\dot{a}(\boldsymbol{\xi}, t) \geq 0 \text{ for all } (\boldsymbol{\xi}, t) \quad (3a)$$

$$\dot{a}(\boldsymbol{\xi}, t) = 0 \text{ for } t < T(\boldsymbol{\xi}) \quad (3b)$$

where $t = T(\boldsymbol{\xi})$ gives the boundary of the area where slip is permitted (due to some chosen causality condition) at time t . Note that $t = T(\boldsymbol{\xi})$ is not necessarily the actual rupture front, which should not generally be assigned a priori, but shown to

be determined as part of the solution, as was done by Das and Kostrov (1990), Henry et al. (2000), and others studies using this method.

$$\int_0^\infty dt \iint_{\Sigma} \mu(\boldsymbol{\xi}) \dot{a}(\boldsymbol{\xi}, t) dS = M_0 \quad (3c)$$

where M_0 is the seismic moment and μ is the modulus of rigidity of the medium. The constraint (3a) is the “no-back-slip” constraint or the “positivity” constraint, and the constraint (3b) is a “causality constraint,” which could be taken as the P - or S -wave causal front, or any other chosen region. The constraint (3c) is the “seismic moment constraint.”

We restrict this discussion to long-period body waves at teleseismic distances (“far-field”) because they are less sensitive to the details of Earth structure. This problem has been looked at using ground motion data from seismograms located at regional distances from earthquakes, for example, for the 1985 Mexican earthquake (Mendoza and Hartzell 1989) and the 1992 Landers, California, earthquake (Cohee and Beroza 1994; Wald and Heaton 1994), but the problem has not yet been considered for the case of true “near-field” data where the higher order terms are kept in the Green function calculations. The Green functions W_j for the teleseismic problem can be calculated using, for example, the ray approximation and the Thomson-Haskell technique or ray-tracing methods to account for the layered crustal structure at the source and the station. These techniques take into account all surface reflections near the source and at the receiver, such as pP , sP , pS , and sS , as well as all reflections and transmissions at every layer of the crustal structures. For the numerical solution, the integrals in (2) must be discretized. For this, the area Σ where slip is permitted must be divided into a number of cells (usually square or rectangular) and $\dot{a}$ within each cell approximated by linear functions in time and along strike and dip (if the width of the cells are small, the variation along dip can be taken as constant). The W_j 's must then be integrated over each cell (analytically, if possible, as done by Das and Kostrov (1990, 1994)) and the integrals over the fault area replaced by sums. The time at the source is discretized by taking a fixed time step, Δt say, and it could be assumed that the slip rate $\dot{a}$ during the time step is a constant, or varies in some prescribed way, say, linearly with time. Both the fault area and the total source duration should be determined as part of the inversion process. One can use the aftershock area as starting area, and then refine it further during the inversion. The initial source duration cannot be longer than the longest record used, in other words, the time length of the seismograms used need to be long enough to study the entire source process. It is important to keep in mind that at many distances other phases, such as core reflections, arrive within this time window, and either the seismogram

used has to be terminated just before this time or these additional phases correctly modeled. Unfortunately, often, neither is done in some studies, based on the incorrect assumption that core reflections are always small compared to the direct arrivals. The seismograms are sampled at some chosen time step Δt_1 , not inconsistent with the spatial cell size of the fault and time step of the source duration. Then Eq. (2) takes the form

$$A\mathbf{x} \approx \mathbf{b} \quad (4)$$

where A is the matrix obtained by integration of W_j , each column of A being a set of Green function seismograms for all stations corresponding to different cells and time instants of the source duration, ordered in the same way as the observed seismograms. The arrangement of Eq. (4) is shown in Fig. 1.

Different stations and components can be weighted differently in Eq. (2). This is very useful when inverting P- and S-waves simultaneously.

For the discrete problem, the positivity constraint (3a) becomes:

$$\mathbf{x} \geq 0, \quad (5a)$$

the inequality meaning that every component of $\mathbf{x}$ is non-negative. The causality constraint (3b) can be replaced by

$$x_i = 0 \quad (5b)$$

for those i corresponding to cells and time samples outside the “rupture front” and the seismic moment constraint (3c) becomes:

Earthquake Rupture: The Inverse Problem, Fig. 1 A simplified example of the matrix A for the inverse problem. (a) Schematic map of the unilateral fault used in the inversion. It has three numbered spatial cells along the fault strike and one cell along its down-dip width. The rupture initiates at time-step 1, in cell 2, and proceeds to the left, breaking cell 2 and then cell 3. The azimuths to three stations (U, V, W) are shown by arrows. (b) Schematic showing the arrangement of the linear system $A\mathbf{x} = \mathbf{b}$ for this problem. In the matrix A , containing the concatenated Green functions, portions relating to the cells 1, 2, and 3 drawn in red,

green, and blue, respectively. The unknown vector $\mathbf{x}$ is the slip rate in each cell 1, 2, or 3, at time-steps 1, 2, and 3 and, in this simple example, has seven elements. In reality, there will be many more time steps, and A will have many more columns. Since only cell 1 is allowed to slip at the first time step, by invoking the causality condition the unknown slip rates x_{11} and x_{13} are zero, and hence excluded from the linear system. The vector of seismograms $\mathbf{b}$ consists of the seismograms at the stations, placed one after another, but having the appropriate sample length consistent with the l.h.s. of the equation

$$\sum c_i x_i \approx M_0 \quad (5c)$$

where c_i is time-independent and for each cell is equal to the product of the average rigidity multiplied by the area of the cell. So, the inverse problem has been reduced to the solution of the linear system (4) under one or more of the constraints (5a), (5b), (5c). In the system (4), the number of equations, m , is equal to the total number of samples taken from all the records involved and the number of unknowns, n , is equal to the number of cells multiplied by the number of time steps at the source. We shall take $m > n$ to reduce the influence of the noise contained in the observations $\mathbf{b}$ on the solution. Then, the system (4) is overdetermined and we can only obtain a solution $\mathbf{x}$ which provides a best fit to the observations, under constraints (5). It is important to note that, in theory, for the constrained system, it is not necessary for $m > n$, though it has been so in all actual studies of earthquakes.

It is now well understood that the matrix A can be ill-conditioned which implies that the system (4) admits more than one solution, equally well fitting the observations. The constraints (5) are introduced for the purpose of reducing the set of permissible (feasible) solutions. When a “best-fitting” solution is obtained, other solutions almost satisfying the equations are also of great interest. This is because the data used in geophysical applications often contains noise and the models used are themselves approximations to reality, so that the “best-fitting” solution may not represent actuality. In addition, though the different solutions may be very close together in data-space, it is possible that they may be somewhat different in model-space, that is, they may physically represent rather different solutions. Thus, more than one solution must be found and the set of (almost) equally well-fitting solutions examined to find features common to the set of solutions, as was done by Das and Kostrov (1990), Henry et al. (2000), and others studies using this method. Das and Kostrov (1990, 1994) also suggested additional tests to determine the robustness of such features. Only features clearly required by the solutions should be interpreted in a geophysical context, as was done in the specific examples discussed below.

For the system of equations (4) together with the constraints (5) to comprise a complete mathematical problem, it is necessary to formulate the exact form of what the “best-fit” to observations means. We include here only constraint (5a) in the mathematical formulation for the sake of simplicity, the inclusion (5b) and (5c) being simple, and is discussed, for example, by Das and Kostrov (1990, 1994). We have to minimize the vector of residuals:

$$\mathbf{r} = \mathbf{b} - A\mathbf{x} \quad (6)$$

For this purpose, some norm of the vector $\mathbf{r}$ must be adopted. One may choose to minimize the ℓ_1 , the ℓ_2 or the

ℓ_∞ norm, all three being equivalent in the sense that they tend to zero simultaneously. Hartzell and Heaton (1983) used the ℓ_2 norm to solve the optimization problem with the positivity constraint, employing computer programs in Lawson and Hanson (1974). Das and Kostrov (1990, 1994) have used the linear programming method (Press et al. 1986) to solve the system (4) and minimize the ℓ_1 norm subject to the condition (5a). The ℓ_1 norm is considered more robust (Tarantola 1987), and Hartzell et al. (1991) have investigated the effect of minimizing different norms on the solution and have shown that the most robust features are properly obtained in the solutions, whichever norm is used. Das and Kostrov (1990, 1994) have checked that when the ℓ_1 norm is minimized, the ℓ_2 and the ℓ_∞ norms for the solution are also small.

In reality, the actual scales at which the rupture propagation takes place in the Earth is microscopic whereas the inverse problem must be solved using finite grids. Therefore, it is important to consider how well the inverse solution obtained gives a picture of the actual solution. To do this, it is necessary to decide how large the cells in the inversion should be. Clearly, the smaller the cells, the better the approximation to the integral equation being solved (Eq. 1) but the larger the number of unknowns. On the other hand, though the approximation to the integral equation improves by going to smaller and smaller cells, the condition number of the matrix A increases (due to columns becoming very similar) making the problem more and more unstable. As pointed out by Backus and Gilbert (1967), since the amount of data is finite, the problem of finding a continuous function from it is indeterminate. Das and Suhadolc (1996) and Das et al. (1996) have suggested that synthetic tests using artificially created data should be used to best estimate the spatial and temporal grid sizes and that the spatial and temporal grid sizes should be consistent. Henry et al. (2000) have also compared the Green functions obtained using various grid sizes to aid in the grid size selection. Sarao et al. (1998) have studied the effect of non-uniform seismic station distribution around the earthquake epicenter.

Constraints from Laboratory Experiments

As mentioned earlier, advanced technological developments has led to major improvements in laboratory experiments on rupture propagation. One important result is the demonstration that ruptures can not only exceed the shear wave speed of the medium but can even reach its compressional wave speed value. Though super-shear ruptures

speed had been found in laboratory experiments as far back as the 1970s (Wu et al. 1972), since these experiments were conducted on plastic polymer, under very low normal stresses, this was considered unrealistic for real earthquakes – both the material and the low normal stress – and the results were ignored. In the late 1990s to the early 2000s, a group at Caltech, led by Rosakis, measured earthquake speeds in the laboratory, not only exceeding the shear wave speed (Rosakis et al. 1999; Xia et al. 2004) but even reaching the compressional wave speed (Xia et al. 2005). The validity of such experiments was confirmed by Mello et al. (2010), who compared velocity and acceleration records from the 2002 M_w 7.9 Denali, Alaska, earthquake at a station close to the fault with those found in the laboratory experiments. Though these experiments were carried out on man-made material (Homalite) under normal temperature and pressure, they revolutionized our way of thinking.

To mimic more realistic conditions, a group led by Schubnel at the École Normale Supérieure (ENS) in Paris has carried out experiments on rock samples (Westerly granite) and obtained super-shear rupture speeds (Passelègue et al. 2013). The rupture front position was obtained by analysis of acoustic high-frequency recordings on a multistation array. This is clearly very close to the situation in seismology, where the rupture details are obtained by seismogram (time-series) analysis, as discussed earlier.

In the real Earth, earthquake ruptures propagate through material at higher temperatures and pressures than those in these experiments, causing lower crustal, intermediate, and deep earthquakes. The same group at ENS has started looking at this problem in the laboratory (Schubnel et al. 2013) by simulating the nucleation of acoustic emission events that resemble deep earthquakes. These events are caused by an instantaneous phase transition from olivine to spinel, which would occur at the same depth and result in large stress releases observed for some deep earthquakes. Now this group has installed laboratory equipment which can reach pressures of 4GPa and temperatures of 1100 °C. For the larger samples, this would simulate conditions in the Earth approximately at 15–20 km depth. On smaller size samples, this would cover the 20–100 km depth range. Thus, in future we will be able to better simulate ruptures at the depths where earthquakes actually occur, thereby improving our understanding of such earthquakes. From the practical point of view, the idea that only crustal earthquakes cause damage to the built environment is not true. The 1970 M_w 7.8 Peru earthquake occurred at a depth of 45 km (International Seismological Centre Bulletin), and killed more than 66,000 people and completely devastated the city of Huaraz, Peru. It remains till today the worst natural disaster in the

western and southern hemispheres of the Earth. Thus, study of sub-crustal earthquakes also has important societal implications.

Discussion of Results of Inversion

Finally, we discuss some examples of what we have learned regarding the mechanics of the earthquake source from the solution of such inverse problems. The first great earthquake which for which the slip history and distribution was obtained was the great 1985 M_w 8.0 Michoacan, Mexico, earthquake (Mendoza and Hartzell 1988). It was found that the main slip took place in two patches on the fault and that aftershocks occurred in the regions of low fault slip or regions of transition from high to low slip, that is, where stresses were increased due to the earthquake. Some studies since then have been summarized by Das and Henry (2003), and many earthquakes have taught us important, and often unexpected, features of earthquake mechanics.

Super-Shear Wave Rupture Speeds

One very important outcome of the study of the inverse problem of earthquake source mechanics has been the result that actual earthquakes can have rupture speeds exceeding the shear wave speed and can even approach the compressional wave speed of the medium. Robinson et al. (2006a) found this when studying the >400 km long strike-slip 2001 M_w 7.8 Kunlun, Tibet, earthquake, which propagated for nearly 100 km at this very high speed. The fault geometry was shown to be a controlling factor for the changes in rupture speed (Robinson et al. 2006a), with the longest, straight portion of the fault having the fastest rupture speed (Fig. 2). The off-fault regions of the super-shear portions of this earthquake had great damage (Bhat et al. 2007), and this again has obvious important implications for earthquake hazard mitigation. By inspecting all long strike-slip faults in the world, and noting their long straight portions, Robinson et al. (2010) made a list of all faults likely to have sustained super-shear rupture and called them “earthquake fault superhighways.” Das (2015) compiled a list of earthquakes known to rupture at super-shear speeds and discussed its importance for seismic hazard assessment and for earthquake engineering applications. Table 1 gives an updated list of crustal earthquakes known to have reached these speeds, and Table 2 the list of earthquake fault superhighways.

Earthquake Rupture Complexity

Another result that has come from the study of inverse problems is the complexity of earthquake ruptures. Forward modeling had shown that such complexity can exist (see,

Earthquake Rupture: The Inverse Problem, Fig. 2 The 14 November 2001 M_w 7.8 Kunlun, Tibet, earthquake. (a) (top) Tectonic setting and topography. The star indicates the epicenter. (bottom) Segmentation of the Kunlun fault is shown by vertical blue dashed lines, together with the CMT solution (red) obtained by Robinson et al. (2006a). The Harvard CMT solution for the 8 November 1997 Manyi earthquake is shown in

blue and the focal mechanisms of two earlier earthquakes in the region with magnitudes >7 are shown in black. The faulting extent in the 2001 Kunlun earthquake is shown in red. (b) Relocated aftershocks for the 6-month period following the earthquake are shown by gray dots, together with their 90% confidence error ellipses. The two faults on which rupture occurred are marked (in red) as MKF (Main Kunlun

e.g., Das and Kostrov 1988). Detailed analyses of body wave seismograms have now shown that such complexity does exist in real earthquakes (Das and Henry 2003). For example, Henry et al. (2000) showed that the 1998 M_w 8.1 Antarctic Plate earthquake jumped over a barrier of width as large as 70–100 km, with a time delay of about 40s, and then

continued propagating for about another 60 km, this second earthquake itself having a M_w 7.6–7.8 (Fig. 3). Both this complexity and the pattern of aftershocks is controlled by preexisting fracture zones on the ocean floor. The great 2001 M_w 8.4 Peru earthquake (Fig. 4) showed how a barrier on the fault could stall the rupture process (Robinson et al.

Earthquake Rupture: The Inverse Problem, Table 1 Strike-slip earthquakes known to have reached super-shear rupture speeds

Year	M_w	Location	Super-shear segment length	Data used	Reference

Earthquake Rupture: The Inverse Problem, Fig. 2 (continued) Fault) and SF (Secondary Fault). The star shows the rupture initiation region. Available CMT solutions are shown in green. Schematic graphs showing the final slip on the two faults are shown as blue lines, with the

rupture speeds in the three phases of rupture on the MKF indicated at the top. The central portion is where rupture reached the compressional wave speed of ≈ 6 km/s. (Figure based on Robinson et al. (2006a))

2006b). Based on marine geophysical data from the portion of the Nazca plate that was subducting in this region, this barrier was identified as being due to bathymetry (such as seamounts located on the inner corner of a fracture zone) related to a subducting fracture zone. Robinson and Cheung (2010) found that barriers limited the faulting extent of the 2003 M_w 8.3 Tokachi-Oki, Japan, earthquake and that the

regions of high slip (“asperities”) aligned with other seamounts on the subducting plate about to enter the trench (Fig. 5). The fact that all the earthquakes mentioned in this section are oceanic is simply due to the fact that many such earthquakes have occurred in the last three decades, and does not imply that earthquakes on land do not have complexity!

Earthquake Rupture: The Inverse Problem, Fig. 3 (a) Tectonic setting of the 25 March 1998 M_w 8.1 Antarctic Plate earthquake. Marine gravity anomalies are from an updated version of Sandwell and Smith (1997), illuminated from the east, with contours every 20 mGal. The relocated aftershocks for a one-year period following the earthquake are shown as white diamonds, the main shock epicenter being the black star. Background seismicity for the period January 1, 1964, to July 31, 1997, is shown as white circles. Selected linear gravity features are identified by white lines and are labeled F1–F6. F1a is the southward continuation of F1. (b) (Top) Principal features of the main shock rupture process. Arrows show location and directivity of the two sub-events and are labeled with start and end times of rupture segments, obtained by Henry et al. (2000). Focal mechanisms are shown in green for the initiation, the first sub-event plotted at the centroid location obtained in

the study of Henry et al. (2000), and for the second sub-event. The open triangle shows the Harvard CMT centroid location. Epicenters shown in (a) which fall in the region of this map are shown in gray. Linear gravity features F1a, F3a, and F4–F6 are shown as solid gray lines. T1a and T3a (dashed lines) are the locations of tectonic features inferred by Henry et al. (2000). (Bottom) Final moment distribution for the preferred solution of Henry et al. (2000) shown as black line graph, with the baseline of the graph being the physical location of the fault. The peak moment density is $1.25 \times 10^{19} \text{ N m km}^{-1}$. Regions of the fault with <15% of this maximum value are excluded in this plot. Same gravity anomalies, same linear features, and same epicenters as Fig. 3(a), except that now only earthquakes which are located with the semi-major axis of the 90% epicentral confidence ellipse <20 km are shown. The white lines show known isochrons

Earthquake Rupture: The Inverse Problem, Fig. 4 (a) Tectonic setting of the 23 June 2001 M_w 8.4 Peru earthquake, together with bathymetry constructed from a GEBCO (2003) $1' \times 1'$ grid. The rupture zone of the earthquake is shown as a pink rectangle and the epicenter by a yellow star. Rupture areas, magnitudes, and years of earlier great earthquakes in the region are indicated by ellipses. (b) The rupture process of this earthquake. The red and green lines show the rupture process, the

numbers indicating the seconds after rupture initiation. The green ellipse shows the region where large slip was induced by delayed rupture of the trapezoid-shaped barrier, shown by green dashed lines. A second rectangular barrier to the southeast is shown by green dashed lines. The moment-rate function is shown on the upper right in blue, with its abscissa having units of 10^{19} Nm/s. (Based on Robinson et al. (2006b))

Large Earthquakes on Transform Faults

Another result from the analysis of seismograms by solving the inverse problem is that transform faults which were thought to be relatively simple can actually be quite complex. Das (2019; ► “Earthquakes on Oceanic Transform Faults, Unexpectedly Large”) has discussed the occurrence of unusually large earthquakes on transform faults. Such faults were believed in the past to have few, small earthquakes. Robinson (2011) studied the 2004 M_w 8.1 Tasman Sea earthquake, a surprising example of a great earthquake on a fossil fracture zone, and showed that due to tectonic changes, such fossil fracture zones can be reactivated by a new stress regime to which the former fossil fracture zone is now subjected.

Another interesting example of an earthquake on a transform fault was the 2000 M_w 7.8 Wharton Basin earthquake in the Indian Ocean. The rupture occurred simultaneously on both nodal planes (Robinson et al. 2001), so the transform fault as well as the ridge both ruptured (see ► “Earthquakes on Oceanic Transform Faults, Unexpectedly Large” for more details).

Summary

In the last three decades, seismologists have solved the “inverse problem” of using broad band digitally recorded seismograms to infer the details of the dynamics of the earthquake rupturing process, including the rupture speed, the slip-rate, and the slip on the fault. The theory and some examples of particular earthquakes showing rupture complexity are given.

Earthquake Sounds

Andrew J. Michael
USGS, Moffett Field, CA, USA

Definition

Earthquake sounds. Atmospheric pressure waves associated with earthquakes, especially those audible to humans.

Introduction

“...previous to an earthquake, a roaring is usually heard,” wrote Lucius Annaeus Seneca, around 65 C.E., in the sixth volume of *Naturales Quaestiones* (translation by Clarke and Geike 1910). While Seneca’s explanations for earthquakes now seem fanciful, this statement remains accurate, and historical records of earthquake sounds have been joined over the last few decades by instrumental studies of this phenomenon.

A particularly interesting case of earthquake sounds concerns the long-reported noises near Moodus, Connecticut, whose town name is derived from a Wangunk word meaning “place of noises” (Brigham 1871). Reports of these noises predate the arrival of European settlers who described them as accompanying shaking “as though in an earthquake” (Davis 1897). Seismographic studies of the earthquakes that accompany the Moodus Noises demonstrate that these sounds are caused by swarms of magnitude -2 to 2.1 events that occur at shallow depths (less than 2.4 km) (Ebel 1982). Similarly, explosive sounds similar to cannon fire have been

documented during earthquake swarms in the lower Rhone Valley of France since 1772 and have now been explained by events with ultra-shallow focal depths of only 200 m. With magnitudes as small as -0.7 , many of these events are heard even if the shaking cannot be felt (Thouvenot et al. 2009).

Because human hearing is an effective spectral analyzer, transforming seismograms to make them audible provides a useful educational tool. And because sound is commonly associated with earthquakes, audio can be an effective element of artistic works about earthquakes. This entry reviews the role of earthquake sounds in science, education, and art.

Records of Sounds

People have reported hearing earthquakes for as long as we have earthquake reports. *The Earthquake Catalogue of the British Association* (Mallet and Mallet 1858) lists reports of earthquake sounds back to 122 B.C.E., although the earliest of these are referenced to histories written by Julius Obsequens in the fourth century C.E.

Catalogs of intensity data are good sources of reports on earthquake sounds. Davison (1938) explored a global set of catalogs, including the Mallet and Mallet catalog mentioned above, and the references in his paper provide a guide to these classic sources. Most of his data came from Britain, and he classified about 20,000 descriptions of sounds into 7 classifications that are largely consistent with low rumbling sounds but also include some descriptions of impulsive sounds which are heard more often at short epicentral distances. A more recent intensity catalog with special emphasis on sounds was collected by Pierre Stahl in the French Pyrenees (Sylvander and Mogos 2005) and the US Geological Survey “Did You Feel It?” catalog of Internet-collected intensity data includes information on sounds in its 1.25 million observations (Wald et al. 1999).

A problem with sounds described in intensity catalogs is that they depend on peoples’ ability to describe an ephemeral experience in words. In the 1979 $M4.0$ earthquake near Bath, Maine, sounds were widely heard and mostly described as high-frequency booms (Pulli et al. 1980). Many respondents described the sound in terms of the explosion of a heating system boiler. One exception was a resident who had actually heard a boiler explode and said the earthquake sounded nothing like that. Regardless of the words used to describe the sound, some residents who had previously lived in Southern California explained that they were different than the longer-lasting, low-frequency rumbles they remembered from earthquakes there. Those descriptions are consistent with Hill et al. (1976) who described earthquake sounds heard in Southern California as “ranging from the rumble of distant thunder to the rushing of a wind.” The high-frequency content of the sounds in Maine could be due to high-frequency ground

motions created by a combination of earthquakes at shallow depths, low crustal attenuation, and relatively high stress drops in that region (Pulli et al. 1980). The Moodus area shares similar characteristics, and thus the shaking should also have substantial high-frequency energy. However, many observers there described the noises in 1981 as “distant thunder” (Ebel 1982). Thus, the subjective observations in intensity catalogs can make interpretation difficult. Because of the vague and varied descriptions of these sounds, it can be difficult to differentiate between sounds caused by earthquakes and other sources such as storm waves, tsunamis, natural and accidental gas explosions, booming sands, and meteorites (Hill 2011).

Interpreting earthquake sounds is also complicated when observers are indoors and may largely hear or record sounds created by the building. For instance, the first known recording of earthquake sounds is from 1954 when a recording that was being made inside a two-story wood-frame dwelling in Eureka, California, accidentally captured an M6.6 earthquake (Steinbrugge 1974). The catalog of earthquake sound recordings compiled by Steinbrugge is available from the Seismological Society of America at https://www.seismosoc.org/inside/earthquake_sounds/. All of these recordings mix together natural earthquake sounds with those produced by man-made structures and human reactions to the shaking. A notable entry in this catalog is a 5-minute recording done by Robert Pate during the 1964 M9.2 Alaska earthquake, including his narration of several minutes of felt shaking.

The first purposeful recordings of earthquake sounds away from man-made structures were made in studies of the 1965–1967 Matsushiro swarm in Japan (Japan Meteorological Agency 1968) and the 1975 earthquake swarm near Brawley, California (Hill et al. 1976). Hill et al. recorded the audio on one stereo channel of an audio cassette tape and the seismic sensor on the other channel. Unfortunately, the seismograms recorded by this analog system were clipped, and that made some of their analysis more uncertain. Sylvander et al. (2007) made digital audio and seismic recordings in the Pyrenees that stayed on scale.

How Are Sounds Produced?

The existence of earthquake sounds is hardly surprising given that seismic waves from the solid earth will refract, albeit weakly, into the atmosphere. This was first demonstrated by Ewing, who considered the simple case of a P-wave in a body of water being transmitted into the atmosphere (Ewing 1883).

As described by Seneca and in the observations cataloged by Mallet and Mallet (1858) and Davison (1938), earthquake sounds are often heard slightly before shaking is felt. Because people often feel the stronger, but later arriving S-wave, this

suggests that the sounds are produced by the P-wave. The instrumental studies referenced above used collocated seismometers and microphones to demonstrate that the sounds coincide with the arrival of the P-wave. The coincidence of the sounds with the arrival of the P-wave demonstrates that the onset of the sounds is generated by transmission of the seismic waves into the atmosphere very close to the listener. This is consistent with Davison’s conclusion that the audible sound and the felt shaking travel at the same velocity. Hill et al. (1976) extended the simple analysis done by Ewing and explored the transmission of sound from a realistic shallow crustal structure to the atmosphere, the frequency content of the shaking from the seismic source, and the sensitivity of human hearing. That analysis showed that the higher frequencies of the seismic shaking overlap with the lower range of human hearing (down to 20 Hz) and are transmitted into the atmosphere with sufficient amplitude to be heard. Both Hill et al. (1976) and Sylvander et al. (2007) observed audio frequencies up to 70 Hz.

Thus, what people hear is in the frequency range of 20 to 70 Hz. These low-frequency sound waves have wavelengths much longer than the size of a human head, and therefore people cannot localize the source of such sounds. The description of earthquake sounds as distant is based on association with other low-frequency sounds that actually are distant, despite that the earthquake sounds are generated close to the listener. It is noteworthy that because earthquake sounds are at such low frequencies, humans are at least as sensitive to these sounds as many animals (Hill 1976).

At Brawley, the later and stronger S-wave arrival was not associated with an audio signal, while at Matsushiro and in the Pyrenees, the S-wave was coincident with sound in some cases. The relative rarity of sound associated with the stronger S-wave shaking can be explained by the attenuation of higher seismic, and therefore audible, frequencies in the S-wave (Hill et al. 1976).

Applications of Sounds

Mallet’s classic study of the Great Neapolitan earthquake of 1857 includes many reports of people hearing the earthquake, and he devotes Part III, Chap. VIII, titled “Of the Sounds that Attended the Shock,” to discussing these observations and attempting to interpret them in terms of a finite source model by drawing an analogy to a long line of troops firing their rifles in succession (Mallet 1862).

Davison’s (1938) study of earthquake sounds attempted to relate his seven classifications to the maximum intensity on the Rossi-Forrel scale, the distance from the event, and the region within which the event occurred. He found that earthquakes were heard over the entire felt area for small

earthquakes but only half of the felt area for larger events and that at greater distances the sound was described as being smoother and more monotonous. The smoother and more monotonous sound with increasing distance is consistent with the attenuation of high-frequency shaking at greater distances from the event. Due to this attenuation, low-frequency motion from large earthquakes is felt at distances beyond the point where shaking in the higher-frequency human hearing range is transmitted. Thus, for large earthquakes, the area of felt shaking is larger than the area where the earthquake can be heard.

More recently, Sylvander and Mogos (2005) and Tosi et al. (2012) developed relationships between the locations where sounds are heard, earthquake magnitude, and epicentral distance and considered sound as a factor in human detection of small earthquakes. Souriau (2006) also explored relationships between heard sounds and shaking and points out that sound may be responsible for waking people and thus could contribute to intensity values at the low end of the scales. That builds on Hill et al.'s (1976) observation that the sound can be audible even when the P-wave is not felt. Tosi et al. (2000) examined whether records of sounds could be used to infer focal mechanisms (the orientation of faults and slip during earthquakes). Partially because the sound observations do not include polarity information, they concluded that the uncertainties were too large to use such data to infer unknown focal mechanisms.

Despite these efforts, it is not clear that earthquake sounds make a significant contribution to the analysis of pre-instrumental earthquakes beyond helping us understand how such sounds contribute to observations of lower intensities. As noted above, there are problems with interpreting subjective reports of sounds that mix together both the natural transmission of shaking into the atmosphere and the shaking of man-made objects. These objections could be removed for future earthquakes by making audio recordings which could easily be integrated into existing digital seismic acquisition systems (Sylvander et al. 2007). Unfortunately, audio recordings may not be a very useful addition to the collocated seismograms because little of the seismic energy is transmitted into the atmosphere and because audio captures only a scalar recording of the three-component ground motion.

While microphones may not be an effective way to record seismic data, seismometers can produce useful records of acoustic waves in the atmosphere that are strong enough to shake the ground. For instance, seismic records of acoustic waves have contributed to forensic seismology investigations into the 1995 Oklahoma City bombing (Holzer et al. 1996), the 1998 truck bombing of the American embassy in Nairobi (Koper et al. 1999), a chemical plant explosion in Nevada (Ichinose et al. 1999), and a pipeline explosion in New Mexico (Koper et al. 2003).

Infrasound

Very-low-frequency acoustic waves known as infrasound can travel great distances through the atmosphere, although with frequencies below 20 Hz, these waves are not audible to humans. Bolt (1964) demonstrated that micropressure recordings after the 1964 Mw 9.2 Alaska earthquake included acoustic waves with periods of 20 to 40 s (frequencies of 0.025 to 0.050 Hz) generated near the earthquake and recorded 3100 km away at Berkeley, California. Donn and Posmentier (1964) further explored these recordings and showed that earlier infrasound arrivals were generated near the recording station by the passing Rayleigh waves. Away from the earthquake, infrasound can also be generated when surface waves travel through mountainous regions. A good review of these mechanisms is Mutschlecner and Whitaker (2005) and the references therein. More recently, Le Pichon et al. (2006) suggested that infrasound could be used to study the amplification of ground displacement by topography, especially in regions with inadequate seismic networks, and Green et al. (2009) demonstrated that coastal cliffs could also be a source of infrasound. An unusual observation is infrasound associated with the tsunami generated by the M9.0 Sumatra earthquake of 2004 (Le Pichon et al. 2005). While infrasound arrays have recorded many earthquakes, their primary applications continue to be the study of phenomena closer to the Earth's surface or in the atmosphere such as volcanoes (Fee and Matoza 2013; Johnson and Ripepe 2011), meteorites (Evers and Haak 2001), and the study of explosions whether chemical or nuclear tests.

Sonification, Education, and Art

Sonification is the process of producing sound from non-auditory data. Most seismic data contains frequencies below human hearing and the simplest way to sonify seismograms is to speed them up, which increases the frequency content, and play them back through an audio system. Benioff mentions doing this with seismograms recorded at slow speed on audio tape (Anonymous 1951), and in 1953 he and Cook Laboratories (Stamford, Connecticut) used this method to produce an LP record with one side called "Earthquakes of this World" (Benioff 1953). Many seismologists have followed in Benioff's footsteps, and this has become particularly easy now that digital seismograms can be converted to audio files using common software such as MatLab. The SeisSound product at the Incorporated Research Institutions for Seismology provides sonified seismograms for many earthquakes (Kilb et al. 2012) and is available online at <https://ds.iris.edu/ds/products/seissound/>.

The human ear is an excellent spectral analyzer, and most people are more used to listening to music than looking at

seismograms. Therefore, sonification of seismograms can be an effective educational tool. Michael (1997) (<https://earthquake.usgs.gov/education/listen/> or <https://doi.org/10.5066/P90ILS3Z>) developed a set of audio playbacks of seismograms that explores how the frequency of shaking varies with source dimension, epicentral distance, and site geology. This web site includes a recording of the 1992 M7.3 Landers earthquake recorded at Mammoth Lakes where local earthquakes were triggered by the passing seismic waves. The local earthquakes are easily heard in the raw sonified seismogram but required filtering to be detected visually in the plotted seismograms (Hill et al. 1993). This demonstrates that audio can be a powerful educational tool.

Sound is a common part of experiencing earthquakes, and so naturally it is part of artistic explorations of seismic events. The seismograms from the above site were used as the basis for my Earthquake Quartet #1 for Trombone, Cello, Voice, and Seismograms (Michael 2000) which is available online at <https://earthquake.usgs.gov/education/listen/music/> or <https://doi.org/10.5066/P9LO2UU2>. Earthquake Quartet #1 starts by describing the earthquake cycle and then explores the idea that society and culture, including music, take place with the earthquakes as an often-ignored backdrop. The earthquakes play the role of percussion because they have abrupt beginnings and broad, non-harmonic, spectra.

Another musical approach was taken by Loos and Scherbaum (1999) in a CD titled “Inner Earth, a seismosonic symphony” which used many different methods of shifting, converting, and transposing seismograms to make them audible. They produced music with harmonic properties that is purely based on seismograms but sounds nothing like the ones that have simply been sped up.

Overlaying a seismogram on a musical staff provides a form of graphical musical notation that can then be played back using synthesized instruments. Some seismograms from the Mt. Etna volcano can be heard as piano music at <http://grid.ct.infn.it/etnasound/page4/page8/page8.html>. The goal of that project was to provide a way to detect changes in the behavior of the volcano by hearing changes in the sonified seismograms (<http://grid.ct.infn.it/etnasound/>), and it also extended into the arts.

The “Great California ShakeOut” earthquake preparedness drills (Jones et al. 2008) use audio combining synthesized earthquake sounds with sounds of damage occurring and sirens to simulate an earthquake experience at the start of the drills. These files can be downloaded from <http://www.shakeout.org/drill/broadcast/index.html>.

“Memento Mori: an internet based earthwork” by Goldberg et al. (1999) used live seismic data to trigger non-seismic audio in a dark installation that also included a visual display of the seismic particle motion. This approach was later used for “Ballet Mori: a ballet conducted by the earth” performed by Muriel Maffre at the San Francisco Ballet to commemorate

the centennial of the 1906 earthquake (Goldberg et al. 2006). Video of the dance can be seen at <http://goldberg.berkeley.edu/art/Ballet-Mori/>.

In 2009, the Parkfield Interventional Earthquake Fieldwork (PIEQF) (Rogers 2010), and online at <http://pieqf.allshookup.org/>, consisted of a large shake table whose motion was triggered by earthquakes throughout the state of California. Both the table itself and a set of rods mounted on the table created noise when an earthquake occurred. This mechanical amplification of the shaking replaced the natural “roaring” discussed by Seneca with a clatter that allowed the viewers to hear distant seismic activity in a way that is not possible through natural shaking and sounds.

Summary

Earthquake sounds form an important part of the earthquake experience and thus are a large part of artistic explorations of these events, but their study forms a small niche within seismology. The last few decades have produced the data necessary to finally understand this phenomenon along with its role in the study of earthquakes and explosions.

Earthquake Source Theory

Raul Madariaga

Ecole Normale Supérieure, Université PSL, Paris, France

Definition

Seismic moment

A measure of the size of an earthquake. In the simplest situation, it represents the moment of the couples of forces that make up a dipolar source. In more general cases, it is a 3 by

	3 symmetric tensor of elementary force couples. For planar faults it is the product of rigidity by slip times the source area.
Seismic radiation	The seismic waves emitted by a seismic source. For point sources these are spherical P and S waves emitted by the point source.
Seismic spectrum	Fourier transform of the seismic waves in the far field from the source. In general, when it is not noted otherwise, it refers to the amplitude of the Fourier transform of the far field displacement.
Kinematic earthquake model	A model of slip history of rupture on a fault determined from near and far field observations. In kinematic models the propagation of rupture is arbitrarily specified.
Dynamic earthquake model	A model of rupture propagation on an earthquake fault based on fracture mechanics.

Introduction

Earthquake source theory studies the dynamics of seismic sources in the Earth. The simplest possible model of a seismic source is that of a point source buried in an elastic medium. A proper understanding of the exact nature of the seismic source took more than 50 years since the first efforts by Nakano and colleagues in the 1920s in Japan. Earthquakes were initially modeled as simple explosions, then as point forces, and, finally, as the result of fast transformational strains inside a sphere. In the early 1950s, it was recognized that P waves radiated by earthquakes presented a spatial amplitude distribution similar to the waves produced by single couples of forces, but it was very soon recognized that this type of source could not explain S wave radiation. The next level of complexity was to introduce a double-couple source, a source without resultant force or moment. The physical origin of the double-couple model was established in the early 1960s. Soon after that finite source models derived from dislocation theory were introduced as a simple way to model observations of seismic radiation. Dislocation models present some severe mechanical problems that we will discuss later. They were soon replaced by more mechanically sound models based on dynamic shear cracks. These are the two kinds of models that are currently being used to model earthquakes over a broad range of frequencies and length scales.

Point Source Models

The radiation from a point force or Green's function is the fundamental solution of the equation of elastodynamics. With few rare exceptions, seismic sources are due to fast

internal deformation in the Earth, for instance, faulting or fast phase changes on localized volumes. For a seismic source to be of internal origin, it has to have zero net force and zero net moment. It is not difficult to imagine seismic sources that satisfy these two conditions. The simplest such source is an explosion or implosion, but they do not produce shear waves, at least in uniform media. The next group of possible sources is dipoles, quadrupoles, or combinations thereof. Experimental observation has shown that simple dipoles are inadequate models of seismic sources. It is possible however to combine three orthogonal linear dipoles in order to form a general seismic source. These three dipoles represent the principal directions of a symmetric tensor of rank 2 that we call the seismic moment tensor:

$$\mathbf{M} = \begin{bmatrix} M_{xx} & M_{xy} & M_{xz} \\ M_{xy} & M_{yy} & M_{yz} \\ M_{xz} & M_{yz} & M_{zz} \end{bmatrix} \quad (1)$$

This moment tensor has a structure that is identical to that of a stress tensor, but it is not of elastic origin. The off-diagonal elements of the moment represent the torque produced by two point forces of direction i separated by an infinitesimal distance in direction j . The diagonal terms represent linear dipoles, two opposite forces separated by a very small distance.

Radiation produced by a point moment tensor source located at point $\mathbf{r}_0$:

$$\mathbf{M}(\mathbf{r}, t) = \mathbf{M}_0(t) \delta(\mathbf{r} - \mathbf{r}_0) \quad (2)$$

form a set of Green's functions. In a homogeneous, linear elastic medium, these Green's functions are well-known and contain both near-field and far-field terms. The most important are the far-field terms, the radiation observed at large distance from the source. These are:

$$u_i^P(\mathbf{r}, t) = \frac{1}{4\pi\rho\alpha^3} \frac{1}{R} \sum_{jk} R_{ijk}^P(\theta, \varphi) \dot{M}_{jk}(t - R/\alpha) \quad (3a)$$

for P waves and

$$u_i^S(\mathbf{r}, t) = \frac{1}{4\pi\rho\beta^3} \frac{1}{r} \sum_{jk} R_{ijk}^S(\theta, \varphi) \dot{M}_{jk}(t - R/\beta) \quad (3b)$$

for S waves. Here R is the distance from the source to the observer. R^P and R^S are the radiation patterns of P and S waves, respectively; and ρ , α and β denote the density and the P and S wave speeds of the elastic medium. The radiation patterns are different for every element of the moment tensor with its own set of symmetries and nodal planes. We observe

that the far-field signal carried by both P and S waves is the time derivative of the seismic moment components, so that far-field seismic waves are proportional to the moment rate of the source.

Very often in seismology, it is assumed that the geometry of the source can be separated from its time variation, so that the moment tensor can be written in the simpler form:

$$\mathbf{M}_0(t) = \mathbf{M}_0 \Omega(t) \quad (4)$$

where $\mathbf{M}_0$ is a time-invariant tensor that describes the geometry of the source and $\Omega(t)$ is the time variation of the moment, the source time function determined by seismologists, often called also the scalar seismic moment $M_0(t)$. In this case we can now write a simpler form of (3):

$$u_i^c(\mathbf{r}, t) = \frac{1}{4\pi\rho c^3} \frac{1}{R} R^c(\theta, \varphi) \Omega(t - R/c) \quad (5)$$

where c stands for either the P or the S wave velocity. For P waves u_c is the radial component; for S waves it is the appropriate transverse component for SH or SV waves. We observe that the signal emitted by the source in the far field is the derivative of the scalar moment time function $\Omega(t)$. The term $R^c(\theta, \phi)$ is the radiation pattern, a function of the takeoff angle of the ray at the source.

With small modifications designed to take into account smooth variations of elastic wave speeds in the earth, these expressions are widely used to generate synthetic seismograms in the far field. The main changes that are needed are the use of travel time instead of R/c in the waveform (5) and a more accurate geometrical spreading to replace the $1/R$ term. The complete expressions are given by Aki and Richards (2002) and Udias et al. (2014). In most work with local earthquakes, the approximation (5) is frequently used with a simple correction for free surface response.

What does a seismic moment represent? A number of mechanical interpretations are possible. In the previous sections, we introduced it as a simple mechanical model of double couples and linear dipoles. Other authors (Backus and Mulcahy 1976) have explained them in terms of the distribution of inelastic stresses (sometimes called stress “glut”). Let us first notice that a very general distribution of force of internal origin must necessarily derive from a symmetrical seismic moment density of the form:

$$\mathbf{f}(\mathbf{r}, t) = \nabla \cdot \mathbf{M}_0(\mathbf{r}, t) \quad (6)$$

where $\mathbf{M}_0$ is the moment tensor density per unit volume. It is not difficult to prove that such a force distribution has neither net force nor torque. The moment tensor can be understood as stress tensor generated by internal forces as

proposed by Eshelby (1957). From the moment tensor, one can define the associated inelastic strain by:

$$\mathbf{M}_0 = \lambda \theta_I \mathbf{I} + 2\mu \boldsymbol{\varepsilon}_I \quad (7)$$

where $\mathbf{I}$ is the identity matrix in 3D, λ and μ are the elastic constants, and $\boldsymbol{\varepsilon}_I$ represents the inelastic strain at the source. This is the strain that would occur in the body in the absence of elastic forces. We can now define $\boldsymbol{\varepsilon}_I$ for a fault segment. Let the source be reduced to a two-dimensional fault element of area dS and thickness h . Then the inelastic strain that occurs across the fault element dS is approximately $\frac{1}{2} D/h$ the ratio of the displacement discontinuity or slip D across the fault by the thickness of the fault. Thus $\varepsilon_I h \rightarrow D/2$ as h decreases to zero fault width. For a planar moment distribution, we get a two-dimensional seismic moment distribution:

$$dm_0 = \mu D dS \quad (8)$$

That is, the moment density of a shear fault is just the product of the elastic constant by slip, a classical result obtained by Burridge and Knopoff (1964) using a different argument based on the representation theorem.

Seismic radiation in the spectral domain. In seismically active areas, the waves radiated by earthquakes become quite complex because of multipathing, scattering, attenuation, site response, etc., so that seismograms resemble the source time function $\Omega(t)$ only at long periods. Complexities in wave propagation affect much less the spectral amplitudes in the Fourier-transformed domain. Radiation from a simple point moment tensor source can be obtained from Eq. (5) by straightforward Fourier transformation:

$$u_i^c(\mathbf{r}, \omega) = \frac{1}{4\pi\rho c^3} \frac{1}{R} R^c(\theta, \varphi) \tilde{\Omega}(\omega) \exp\left(-\frac{i\omega R}{c}\right) \quad (9)$$

where $\tilde{\Omega}(\omega)$ is the Fourier transform of the source time function $\Omega(t)$.

From the scaling of moment with earthquake size, Aki (1967) and, from spectral observations, Brune (1970) concluded that the seismic spectra decayed as ω^{-2} at high frequencies. A simple model of the spectral amplitude is:

$$\Omega(\omega) = \frac{M_0}{1 + \omega^2/\omega_0^2} \quad (10)$$

where ω_0 is the corner frequency of the earthquake, the intersection between the low- and high-frequency asymptotes of expression (10). This is the so-called omega-squared model of seismic radiation. In this model seismic sources are characterized by only two independent scalar parameters: the seismic moment and the corner frequency.

As mentioned earlier, not all earthquakes have displacement spectra as simple as this, but the omega-squared model is a good starting point for understanding seismic radiation.

Finite Source Models

Earthquakes are due to the fast propagation of slip on a fault, or fault system, at speeds of the order of that of shear waves. There is evidence that a few earthquakes have propagated at speeds faster than that of shear waves, but these are exceptional events. For most others, the speed of rupture propagation is close to that of Rayleigh waves on the fault. Traditionally, finite source earthquake models are either kinematic or dynamic. In the first class, the distribution of seismic moment and rupture time are specified in order to satisfy certain observational constraints on the source. The most common way is to specify the rupture process based on simple models of rupture propagation, for instance, at constant speed, and then determine the distribution of moment (slip) on the fault from the waveforms observed in different seismic stations. As the data has improved, kinematic inversion methods have become increasingly sophisticated, but the basic problem of how does a rupture grow cannot be determined from basic mechanical principles. The alternative is to use dynamic models where rupture is computed numerically from the specification of the stresses that prevail on the fault and the friction law that acts on the fault surface.

Kinematic Models

One of the most widely used kinematic models was introduced by Haskell (1964). In this model a uniform displacement discontinuity spreads at constant rupture velocity inside a rectangular fault. At low frequencies, for wavelengths longer than the size of the fault, this model is a reasonable approximation to the rupture of a strike slip fault. In Haskell's model at time $t = 0$, a line dislocation of width W appears suddenly and propagates along the fault length at a constant rupture velocity v until a region of length L of the fault has been broken. As the dislocation moves, it leaves behind a zone of constant slip D . Assuming that the fault lies on a plane of coordinates (x, y) , the slip function can be written as:

$$D(x, y, t) = D s(t - x/v) \text{ for } -W < y < W \text{ and } 0 < x < L \quad (11)$$

where $s(t)$ is the source time function that, in the simplest version of Haskell's model, is invariant with position on the fault. The most important feature of this model is the propagation of rupture implicit in the time delay of rupture

x/v , where v is the rupture velocity. An obvious unphysical feature of this model is that rupture appears instantaneously in the y -direction; the other is that near the borders of the fault, slip suddenly jumps from D to zero. This violates material continuity and produces very strong unphysical stress concentrations. In spite of these two obvious shortcomings, Haskell's model gives a simple, first-order approximation to seismic slip, fault finiteness, and finite rupture speed. The seismic moment of Haskell's model is just $M_0 = \mu DLW$. This model has been extensively used to invert for seismic source parameters both in the near and far field from seismic and geodetic data. Some of the limitations of Haskell's model can be removed by admitting that slip is variable on the fault, so that D in Eq. (11) is no longer assumed to be constant but a function of position on the fault. Slip can be tapered as suggested by dynamic models of rupture. Rupture speed can also be made variable.

Dynamical Fault Models

The most frequently used source models are dynamic models, based on some basic concepts of fracture mechanics introduced by seismologists in the middle 1960s. The simplest of these dynamic models is a circular shear crack. This model was introduced by several authors in order to relate fault slip to stress drop inside a fault. A natural approach to model earthquakes was to use well-known results from fracture mechanics. Among dynamic models, we consider here a circular shear crack, assuming that rupture starts from a point and then propagates self-similarly until it finally stops at a certain source radius. This model was carefully studied in the 1970s, and a complete understanding of it is available without the need of getting into the details of the numerical modeling of earthquake sources.

Kostrov's self-similar circular crack. The simplest model of how an earthquake starts is a circular-shaped rupture front that starts from a point and spreads at constant rupture speed v without ever stopping. Slip on this fault is driven by stress drop inside the fault. The solution for slip across the fault, found by Kostrov in 1964, is surprisingly simple:

$$D(r, t) = C(v) \frac{\Delta\sigma}{\mu} \sqrt{v^2 t^2 - r^2} \quad (12)$$

where r is the radius of the fault measured from the point of rupture initiation. vt is the instantaneous radius of the rupture at time t . $\Delta\sigma$ is the constant stress drop inside the rupture zone, μ is the elastic shear modulus, and $C(v)$ is a very slowly varying function of the rupture velocity. For most practical purposes, $C \sim 1$. Inside the fault, for $r < vt$, the stress change produced by the slip function is constant and equal to $\Delta\sigma$. Thus for constant stress drop, slip inside the fault scales with the "ratio of stress

drop over rigidity ‘times’ the instantaneous radius of the fault.” As rupture propagates, displacement around the fault scales with the instantaneous radius of the rupture zone. The dynamic model (12) describes rupture propagation, but it has no mechanism to stop the rupture.

A finite fault model can be developed from Eq. (12) by assuming that rupture suddenly stops after the fault has grown to a certain fixed radius. This simple dynamic model was proposed by Madariaga (1976). The circular crack problem is posed in terms of stresses not of slip, but the rupture process is fixed in advance so that rupture does not develop spontaneously. This is the only unrealistic feature of this model, and it is the reason why it is qualified as quasi-dynamic, that is, rupture is kinematically defined, but slip is computed by solving the elastodynamic equations.

The static circular shear crack. We start by a quick study of a simple circular crack from which we derive some of the most fundamental properties of dynamic source models. Let us consider a static circular (“penny shaped”) crack of radius a lying on the x, y plane. Assuming that the fault is loaded by an initial shear stress σ_0 and that the stress drop $\Delta\sigma$ is uniform inside the fault, slip on the fault is given by:

$$D(r) = \frac{24}{7\pi} \frac{\Delta\sigma}{\mu} \sqrt{a^2 - r^2} \quad (13)$$

where r is the radial distance from the center of the fault, a is the radius of the shear crack, and μ is the elastic rigidity of the medium surrounding the crack. Slip in this model has

the typical elliptical shape that we associate with cracks. The taper of slip near the edges of the crack is the hallmark of dynamic source models. The slip distribution near the edges has a parabolic shape that is closely related to stress concentrations outside the fault zone.

From Eq. (13) we can determine the scalar seismic moment for a circular fault, $M_0 = 16/7 \Delta\sigma a^3$,

so that the moment is the product of the stress drop times the cube of the fault size. This simple relation is the basis of the seismic scaling law proposed by Aki (1967). The circular crack model has been used to quantify numerous small earthquakes for which the moment was estimated from the amplitude of seismic waves and the source radius was estimated from corner frequencies, aftershock distribution, etc.; the result is that for shallow earthquakes in crustal seismogenic zones like the San Andreas fault or the North Anatolian fault in Turkey, stress drops are of the order of 1–10 MPa. For deeper events in subduction zones, stress drops can reach several tens of MPa. Thus, in earthquakes stresses do not change much, at most a couple of order of magnitudes, while source radius varies over several orders of magnitudes from meters to 100 km or more. It is only in this sense that the usual assertion “stress drop in earthquakes is constant” should be taken; it actually changes but much less than the other parameters in the scaling law.

The quasi-dynamic circular crack. There are no simple analytical solutions like (13) for finite dynamic cracks. We are forced to use numerical solutions that are actually very simple to compute. The full solution to the circular crack problem is shown in Fig. 1. Initially, until the sudden arrest

Earthquake Source Theory,

Fig. 1 Slip distribution as a function of time and position for Madariaga’s (1976) quasi-dynamic circular crack model

of rupture at the final radius a , the slip distribution can be accurately modeled using Kostrov's self-similar solution (12). The stopping of rupture generates strong healing waves that propagate inward from the rim of the fault. These waves are of three types: P, S, and Rayleigh waves. Soon after the passage of the Rayleigh waves, slip rate inside the fault decreases to zero and the fault heals. After healing, we assume that frictional forces are sufficiently strong that no slip will occur until the fault is reloaded. As observed in Fig. 1, it is clear that slip and rise time are functions of position on the fault, where the rise time being longer near the center and slip is also larger near the edges of the fault where slip is clamped. Finally, let us note that the slip after healing is very similar to that of a static circular crack, except that there is a slight overshoot of slip with respect to the static solution (13). The overshoot is of course a function of the rupture speed, but its maximum value is of the order of 15% for a rupture speed of 0.75.

Future Work

Seismic observations have steadily improved in the last 20 years due to the wide availability of digital, continuously recording accelerograms that can be integrated to obtain velocity and band-limited displacement fields near active faults. Additional information about rupture is provided by field studies of faulting associated with earthquakes and from geodetic observations. Modeling and inversion of such data have been usually done using kinematic models derived from the original Haskell model. This approach gives solutions that are very non-unique because the rupture process (the rupture velocity) is difficult to estimate. Rupture velocity actually controls seismic radiation, so that poor velocity control leads to poor seismic inversions. There is hope that dynamic models, where rupture is inverted as part of the inversion process, will provide better estimates of the stress field around major fault zones and provide some essential parameters, like the friction law that controls rupture propagation.

Earthquake, Aftershocks

Mian Liu¹ and Seth Stein²

Definition

Aftershocks Earthquakes that follow a large earthquake (the mainshock) in an earthquake sequence.

Introduction

Earthquakes typically occur in sequences that may include foreshocks, the mainshock (the largest event or events), and aftershocks. Earthquake sequences without a clear mainshock are called swarms.

Aftershocks generally refer to the smaller earthquakes that follow a mainshock within certain spatial and temporal windows. However, the criteria for choosing these windows are somewhat arbitrary. Typically, aftershocks are defined within an area around the mainshock's source region (i.e., the ruptured fault segment, which is about 50–100 km long for a magnitude 7.0 earthquake). Most aftershocks occur on the main rupture surface; hence, they are often used to define the complex geometry of the rupture plane. However, in many cases, especially for earthquakes in subduction zones, the aftershock area increases significantly following the mainshock (Tajima and Kanamori 1985). Some aftershocks also occur off the main rupture surface. Distant earthquakes triggered by the mainshock's seismic waves (see ► [“Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyna, India”](#)) may also be regarded as aftershocks (Gomberg and Johnson 2005). Temporally, aftershocks are defined as elevated seismicity above the background activity following the main shock. This definition

also leaves room for ambiguity, as the background seismic activity can be difficult to define in some places. Aftershocks usually count for less than 5% of the total seismic energy release of the entire seismic sequence (Scholz 2002).

Scaling Laws for Aftershocks

A large earthquake is usually followed by many smaller events (aftershocks); their occurrence rate decreases with time, typically following a pattern known as the Omori's law, named for Fusakichi Omori's observation of the 1891 Nobi earthquake in Japan (Omori 1894) and later modified by Utsu (1961):

$$n(t) = \frac{K}{(c+t)^p}$$

where $n(t)$ is the number of aftershocks by time t after the mainshock; K , p , and c are constants. The value of c is typically positive close to zero, and p close to 1. Hence, the number of aftershocks drops hyperbolically with time (Fig. 1). The values of these constants are obtained by fitting to the data for each aftershock sequence.

It has been observed that the largest aftershock is usually about one magnitude unit smaller than the mainshock independent of the mainshock magnitude. This is known as Bath's law (Bath 1965; Richter 1958). However, because the data selection is retrospective and subjective, the size of aftershocks can vary substantially for different earthquake sequences.

Like all earthquakes, the size distribution of aftershocks follow the Gutenberg–Richter law (Gutenberg and Richter 1954):

$$\log_{10} N(M) = a - bM$$

where $N(M)$ is the number of earthquakes of magnitude $\geq M$, a and b are constants. This relationship plots as a straight line with slope b , whose value, often referred to as the b -value, is typically in the range of 0.8–1.2. For $b = 1$, the number of earthquakes increases by a factor of 10 for every unit drop. The b -value varies in time and space even for the same earthquake sequence. Some studies have suggested that the b -value can be used as a stress indicator, with lower b -values often associated with higher stresses (Schorlemmer et al. 2005).

Causes of Aftershocks

Aftershocks are ubiquitous; they are observed following nearly all sizable earthquakes near the rupture zones of the mainshocks. Such close spatiotemporal relationship with

mainshock indicates that aftershocks result from incomplete rupture and heterogeneous slip (e.g., Bullen and Bolt 1947). This notion is consistent with some case studies that found aftershocks concentrated around the perimeter of the rupture zone or around asperities within the rupture zone where most of the coseismic slip occurred (Beroza 1991; Scholz 2002; Wetzler et al. 2018).

The main causes of aftershocks are thought to include mainshock-induced changes of frictional properties of the fault zone and stress perturbations. Laboratory experiments indicate that frictional properties change with the duration of stationary contact and the instantaneous sliding velocity (Scholz 2002). A constitutive relationship based on such results, known as the rate-and-state law (Dieterich 1979; Ruina 1983), can explain the time-dependent changes of seismic rates that are consistent with the Omori's law (Dieterich 1994). Stress perturbations may arise from creep recovery of rocks in the immediate areas of the fault (Benioff 1951), viscous relaxation from the lower crustal and upper mantle (Lieber and Braslau 1965; Stein and Liu 2009), after-slip (Koper et al. 2018; Ross et al. 2017), and pore-elastic effects (Scholz 2002). In particular, the changes of the Coulomb static stress resulted from the mainshock have been shown to cause spatial migration of seismicity and trigger earthquakes (Parsons 2002; Stein 1999). Other causes may include dynamic triggering (Gomberg and Johnson 2005; Fan and Shearer 2016) and pore fluid flow (Miller et al. 2004; Nur and Booker 1972).

Aftershocks and Earthquake Hazard

Aftershocks can be large and damaging (e.g., Wiemer et al. 2002). The durations of aftershock sequences for plate-boundary earthquakes are typically less than 10 years (Parsons 2002) (Fig. 1). However, aftershock sequences away from plate-boundary faults tend to last longer. In the broadly deforming western United States, for example, aftershocks are found to last 50–100 years. Within the stable continental interior, aftershock sequences may last hundreds of years or even longer (Ebel et al. 2000; Stein and Liu 2009). Such long aftershock sequences in continental interiors, where large earthquakes are infrequent and historic records are often incomplete, could bias hazard assessment.

Further complication may arise from the fact that earthquakes tend to cluster in time and space. Studies of large shallow earthquakes in the world show that these large events often occur in pairs or groups (called doublets or multiplets); the later events, which could be regarded as aftershocks, can be bigger than the triggering event (the mainshock) (Kagan and Jackson 1999). Such clustering patterns are consistent with the view that all earthquakes can trigger their own earthquakes that in turn trigger more quakes,

Earthquake, Aftershocks, Fig. 1 (a) Topography and seismicity (circles, size proportional to magnitude) around the epicenter (star) of the 1989 Loma Prieta earthquake (Mw 6.9) on the San Andreas Fault. Green line marks the fault rupture; red lines enclose the spatial window

for the aftershocks. (b) Earthquake occurrence between 1980 and 2010 within the spatial window. (c) Plot of seismicity showing the t^{-1} decay of aftershocks

and the triggered events may be bigger than the triggering event (Helmstetter et al. 2003; Ogata 1998). Because the triggered events (the aftershocks) statistically follow the Omori's law, statistical models can be developed to assess time-dependent probability of future damaging earthquakes after each event (Gerstenberger et al. 2005; Jones 1985; Page et al. 2016; Reasenberg and Jones 1989).

Summary

Aftershocks are earthquakes that follow the mainshock in an earthquake sequence. They are typically smaller than the mainshock and occur on or near the rupture plane of the mainshock, resulting from changes of stress and frictional properties of the fault zone caused by the mainshock. The duration of aftershock sequences is typically a few years for earthquakes at plate boundaries, but can last much longer within stable continental interiors.

Earthquake archaeology

Definition

The study of pre-instrumental earthquakes that, by affecting locations of human occupation and their environments, have left their mark in ancient structures uncovered by means of archaeological excavations or pertaining to the monumental heritage (Buck and Stewart 2000; Galadini et al. 2006).

Introduction

Ever since man-made structures have been erected, earthquakes have left their marks on these constructions. However, damage in archaeologically excavated buildings or continuously preserved monuments is often hard to unravel in terms of the causative effects. The use of archaeological data to investigate unknown or poorly known historical earthquakes and descriptions of earthquake effects was recorded in the archaeological heritage started in the nineteenth and early twentieth centuries (e.g., De Rossi 1874; Schliemann 1881; Evans 1928). Since the 1980s, the increased interest in the subject led to the publication of special volumes and articles in seismological and geological journals (e.g., Guidoboni 1989; Stiros and Jones 1996; McGuire et al. 2000; Galadini et al. 2006; Reicherter et al. 2009; Jusseret and Sintubin 2017). While earlier investigations were dominated by the qualitative description of damage records, more recent studies take a quantitative approach (e.g., Hinzen et al. 2018). The main questions to be answered by archaeoseismic investigations are the following: (1) How probable are seismic ground motions, or secondary earthquake effects, as the cause of

damage observed in man-made structures from the past? (2) When did the damaging ground motion occur? (3) What can be deduced about the nature of the causing earthquake?

Archaeoseismic Observations

The marks in ancient structures relevant for archaeoseismology fall into four main categories: (1) displacements along shear planes directly linked to the earthquake fault plane or side branches of it. In particular, earthquakes with a strike slip mechanism can leave distinctive traces in buildings and lifelines such as aqueducts, roads, and sewer systems. Case studies (e.g., Ellenblum et al. 1998; Meghraoui et al. 2003) show that under favorable conditions, the amount of slip and in case of repeated events the slip rate of the faults can be revealed. (2) Off-fault shaking effects including fractured building elements, tilted walls, shift of building elements, lateral warping, breaking and overthrowing of walls, and rotations of vertically oriented objects (tomb stones, columns, monuments). For most of these features, a seismogenic origin is not the only possible interpretation. Therefore, alternative causes must be taken into account in the damage analysis. (3) The secondary shaking effects lateral spreading and cyclic mobility as a consequence of liquefaction of the subsurface. Liquefaction always requires a certain level of dynamic excitation. So secondary damages in buildings and monuments due to liquefaction help exclude alternative causes from a damage scenario. (4) Archaeologically detected abandonment of a site and evidence of repair and rebuilding. These observations are mainly of interest in connection with the reasons mentioned before, because as a single observation in general, they do not give enough evidence for the conclusion of a seismogenic cause (Galadini et al. 2006).

While the first category is limited directly to the linear features of active faults, off-fault shaking affects a much larger area and is more common but harder to prove. Ancient structures show deformations related to seismic shaking similar to those observed in recent earthquakes. Typical earthquake effects on masonry walls are (1) cross fissures, due to stress concentrations often nucleating at corners of doors and windows, driven by shear forces; (2) corner expulsion of walls caused by differential movements in orthogonal directions; (3) horizontal and independent lateral and rotational shift of wall blocks, best visible in uncemented walls made of rectangular blocks; (5) spall of block corners due to stress concentrations; (6) height reduction by vertical crashing; (7) movement of keystones and rupture of arch piers; (8) rotation of vertically oriented objects; and (9) domino-like toppling of structured columns and walls. Examples are shown in Fig. 1. Following the term *seismite*, used for seismically disturbed sediment layers, the abovementioned deformations

may be called *archaeoseismites*. Several of these deformations may also originate without dynamic earthquake excitation. In these cases, a single piece of evidence, or at a single edifice only, cannot be considered a conclusive *archaeoseismite*. If damage is identified as *archaeoseismites*, intensities can be derived following the classical macroseismic methods. For arches affected by earthquake ground motions, Hinzen et al. (2016) introduced a specific rating scheme.

Methods

Archaeoseismology requires the integration of several scientific disciplines. Figure 2 shows a scheme of workflow in a quantitative archaeoseismic study. Besides archaeological and seismological methods, input from geodesy, pure and applied geology, and civil engineering is needed (Ambraseys 2006). Physical absolute dating techniques including radiometric methods, luminescence methods, and dendrochronology are necessary to determine a time window for the damaging event. In case of multiple events, the rough dates are crucial for seismicity models and hazard analysis.

The first step in studying field cases is the documentation and analysis of damage to the archaeologically excavated buildings or objects. In addition to the important traditional excavation techniques and classical measurements and drawings, 3D imaging techniques have proved their usefulness in archaeoseismic field cases. Photogrammetry and laser scanning are fast in the field and allow detailed analysis and post processing, particularly a quantification of deformations, fractures, etc. In cases where building parts are fragile and cannot be conserved in the original finding situation, successive laser scans during the excavation offer the possibility to build virtual 3D models. In ideal cases, the seismological relevant data can be acquired during an ongoing excavation. Important is the complete documentation of the stratigraphy of debris layers, which can reveal the decay rate of structures (Galadini et al. 2006). Building collapse may be sudden, progressive, or a combination of both. The progressive deterioration of walls results in accumulations having maximum thickness close to the wall feeding the material. The thickness decreases at a short distance from the wall. In case of height reduction of walls or buildings due to earthquake effects, the debris is more distributed. Sometimes even complete walls topple to one side; in this case the impact pattern can help to constrain ground motion amplitudes. However, if the findings of previous excavations are archaeoseismologically analyzed, the current situation and available excavation reports form the database. Possible alterations of the excavated objects since the first excavation and shortcomings in the documentation, especially if earthquake actions were not considered at the time of the original excavation, might hinder the interpretation (Hinzen et al. 2018).

Earthquake, Archaeoseismology, Fig. 1 Examples of deformations and damage which possibly are earthquake effects: (a) horizontally deformed wall of a crusader fortress build on top of the Dead Sea Transform Fault in the Jordan Valley; (b) deformed vault of a Roman sewer in Cologne, Germany; (c) toppled columns of a Byzantine church in Sussita located above the Sea of Galilee; (d) toppled column of the great palace in Patra, Jordan; (e) moved block in an arch of the Nimrod

fortress in the Golan Heights; (f) shifted blocks of an analemma of a Roman theater in Pinara, SW Turkey; (g) moved blocks of a corner wall of a Roman monument in Patara, SW Turkey; (h) shifted blocks of a Roman grave house in Pinara, SW Turkey; (i) spall of block corners, same object as in (g); (j) broken and horizontally displaced fortification wall of the Roman Tolbiacum (Zülpich, Germany); (k) rotated Lycien sarcophagus in Pinara, SW Turkey

Depending on site conditions, exploration and modeling of the properties of the local geology at the site are an important second step. Several of the abovementioned deformations can also be caused by slow, quasi-static deformations of the subsoil, and ground amplification due to shallow soft

sediments can significantly amplify seismic shaking. If the latter is not taken into account, the size of the damaging earthquake can easily be overestimated.

Only on rare occasions, site-specific strong motion records from recent earthquakes will be available and help to prove or

Earthquake, Archaeoseismology,

Fig. 2 Schematic workflow in a quantitative multidisciplinary archaeoseismic study. The dynamic behavior is studied by finite element (FE) or discrete element (DE) methods

disprove proposed damage scenarios. To overcome this lack of information, the calculation of synthetic seismograms based on models of the capable faults and local geology has been used to better ascertain the probability of a seismogenic cause of the damages and name faults on which the damaging earthquake occurred. When other natural forces (flooding, storm, mass movement) or even human action also come into consideration, their action on the excavated objects has to be tested as well.

Reconstructions of the damaged archaeological objects are the basis for determining the dynamic behavior and the vulnerability of the ancient buildings. Common earthquake engineering techniques including finite element and discrete element modeling are used to analyze the reaction of the buildings to the estimated seismic loading functions. Results from such models are compared to the damages observed in situ.

The most challenging task of an archaeoseismic study is the determination of source parameters of the earthquake, which caused the analyzed damages. While timing of the earthquake has to be done by archaeological techniques including classical archaeological stratigraphy and the abovementioned physical dating, location and strength of the earthquake can only be narrowed down with seismological models. A territorial approach (Galadini et al. 2006) in which the collected information from the surroundings of an archaeological site are taken into account is the most promising tool to determine earthquake source parameters.

Recent studies have shown that precariously balanced archaeological structures can be treated in the same way as precariously balanced rock, which can give an estimate of ground motion levels at a site that have not been reached or exceeded. Schweppe et al. (2017) explored the potential

of this method by applying it to the remains of a Roman temple in Israel.

Summary

In the past decades, archaeoseismology has evolved as a new branch of seismological sciences. While palaeoseismology focuses on the marks left by earthquakes in the geological record, archaeoseismologists analyze and interpret marks in the archaeological record and/or in preserved monuments.

The use of quantitative methods in archaeoseismology, including calculation of synthetic site-specific strong motion seismograms, modeling of natural non-earthquake-related forces, anthropogenic forces, and finite or discrete element models of structures, supports conclusive discrimination between potential damage scenarios. However, if model parameters cannot be well constrained, modeling result uncertainties might still be too large to draw definite conclusions. Common sense interpretations of archaeoseismites as solitary evidence are generally too vague to complement earthquake catalogs for a seismic hazard analysis. Recent advances in ground motion simulation methods and computational possibilities promise to refine quantitative archaeoseismological methods and establish them at levels equal to historical and palaeoseismological methods. Finally, even if an archaeoseismic study does not deliver the often-requested improvement of hazard determination, it can still advance our picture of the past by attempting to answer open archaeological, historical, and geologic questions in a scientific manner. And following Ambraseys (2006), surveying and mapping an archaeological site is an art; verifying the cause of damage is science.

Earthquake, Focal Mechanism

Emile A. Okal

Department of Earth and Planetary Sciences, Northwestern University, Evanston, IL, USA

Definition

Focal mechanisms are geometrical or mathematical representations of the faulting during an earthquake. In very simple terms, the latter consists of the relative motions of two blocks of Earth called *walls* along a planar surface called *fault*. Figure 1 shows that the description of an earthquake rupture needs three angles. The *strike* angle ϕ is the azimuth (with respect to North) of the trace of the fault on a horizontal plane such as the Earth's surface; the *dip* angle δ characterizes the steepness of the fault, and the *rake* or *slip* angle λ , the direction of motion, within the fault plane and relative to the horizontal, of the hanging wall relative to the foot wall. A full description of the earthquake rupture requires an additional scalar, related to the length of slip of the fault walls, and thus to the size or *magnitude* of the event.

Representation by a Double-Couple

As such, an earthquake source, described by three angles and a scalar, is a more complex mathematical entity than a simple vector (described by two angles and a scalar) and in particular cannot be represented physically by a single force. Vvedenskaya (1956), followed in the West by Knopoff and Gilbert (1959), introduced the concept of the double-couple, a system of forces shown on Fig. 2 and consisting of two opposing torques of equal moment M_0 ; this system has no dynamic effect (translation or rotation) on a rigid body but results in the deformation of a medium of finite rigidity.

The representation theorem (e.g., Aki and Richards 1980, pp. 38–41) considers an elastic medium of rigidity μ and states that a dislocation with slip Δu (in the direction $\hat{\mathbf{d}}$) along a fault of surface Σ cut into the medium (Fig. 2a) will generate the same field of dynamic deformation (expressed as seismic waves) as a double-couple of moment $M_0 = \mu \Sigma \Delta u$, embedded in the medium in the absence of the cut, with the direction of forces and levers in Fig. 2b along those of the slip, $\hat{\mathbf{d}}$, and of the normal to the fault plane, $\hat{\mathbf{n}}$.

The double-couple shown in Fig. 2b separates the space around it into four quadrants containing respectively the heads and tails of the arrows. They are delineated by the fault plane and the plane normal to the slip $\hat{\mathbf{d}}$. In quadrants I and III, the seismic motion will be “*anaseismic*,” or away from the source, while in II and IV, it will be “*kataseismic*” or

Earthquake, Focal Mechanism,

Fig. 1 (a, b) Before and after sketches of the displacement of fault blocks during an earthquake. The fault plane is shaded in (b). (c) Definition of the strike, dip, and slip angles, ϕ , δ , λ , respectively, in the geometry of the rupture represented at left. The unit vector $\hat{\mathbf{d}}$ represents the direction of motion of the hanging wall (not represented to prevent clutter) with respect to the foot wall. (c: After Stein and Wysession 2003)

Earthquake, Focal Mechanism, Fig. 2 (a) Seismic slip along a fault (represented as the hatched area of surface Σ). The total slip Δu is the difference between the displacements of the top wall (shown as solid arrows) and of the bottom wall (dashed arrows). (b) “Double-couple” system of forces, equivalent, in the unruptured medium, to the dislocation shown in (a). (c) “Beachball” representation of the quadrants defined by the orientation of the double-couple. (a: After Aki and Richards 1980)

toward the source. The quadrants are accordingly shaded black and white in Fig. 2c. Note that in Fig. 2b, c, the source is approximated as a *point* in space, hence the concept of a “point-source double-couple.”

Focal Mechanisms from P-Wave First Motions

Under the high-frequency approximation of geometrical optics, a most remarkable property of *P* waves is the conservation of the ana- or kataseismic character along the entire seismic ray, all the way to a receiving seismic station at the Earth’s surface, where an anaseismic wave results in an initial *upward* motion of the ground, while a kataseismic one gives a *downward* first motion.

This property has been used extensively to obtain earthquake focal mechanisms by gathering first-motion *P*-wave data at large datasets of local and distant stations and backtracking this information along the relevant rays into a mapping of the focal sphere at the source. This amounts to resolving the orientation in space of the diagram on Fig. 2c, known traditionally as a “beachball.” Because of the difficulty of representing a full sphere on a planar figure (long known to world cartographers), and thanks to the symmetry of the beachball, it is convenient and sufficient to represent only a stereographic projection of the *lower focal hemisphere* separated at the horizontal plane and involving rays leaving down into the deep Earth, and eventually emerging at large distances. This constitutes the standard representation of earthquake focal mechanisms. Figure 3 illustrates examples of the most common types of mechanisms.

Note that a change of focal mechanism results in a mere *solid rotation* in space of the beachball pattern but does not change its nature (Fig. 4).

A common feature of the double-couple concept and of its beachball representation is their high level of symmetry. The two planes defining the quadrants on Fig. 2b are conceptually interchangeable, and as a result, there exists an inherent indeterminacy between two possible physical solutions

Earthquake, Focal Mechanism,

Fig. 3 Examples of focal geometries with corresponding beachball patterns. (Adapted from Stein and Wyssession 2003)

Earthquake, Focal Mechanism, Fig. 4 A basketball has been divided into four quadrants alternately painted black and white. By rotating the basketball in space, one can obtain a representation of all possible focal orientations of the double-couple shown in Fig. 2b. This experiment demonstrates that earthquake focal geometries differ only by a solid rotation in space

obtained from any field of seismic data generated by a point source double-couple. For example, a left-lateral strike-slip earthquake on a vertical fault striking North–South is seismically indistinguishable from a right-lateral one on a fault striking East–West. This property, rooted in the symmetry of the double-couple, applies to all seismic waves, including P and S waves, surface waves, and the free oscillations of the Earth. The indeterminacy can be lifted only by considering a source extended in space, as opposed to a point source. In practice, this is done either by using field methods to recognize the orientation of the fault through its expression

on the ground, or by mapping the aftershocks of the event which are expected to occur along the direction of faulting, or by considering the so-called source-finiteness effects in the seismograms, which result from the interference of the elementary sources, distributed both in time and space, as the rupture propagates over the faulting area. In all cases, note again that the fault can no longer be represented as a point source.

Stress Release

In another interpretation of focal mechanisms, one can expand the double-couple as a two-dimensional deviatoric and symmetric tensor:

$$M_{ij} = M_0 \left(\hat{d}_i \hat{n}_j + \hat{n}_i \hat{d}_j \right) \quad (1)$$

where $\hat{\mathbf{d}}$ and $\hat{\mathbf{n}}$ are the unit vectors along the direction of slip, and perpendicular to the fault, respectively. These components and the principal directions of the moment tensor are directly related to those of the stresses released during the earthquake.

In particular, the bisector $\mathbf{T} = \frac{1}{\sqrt{2}} (\hat{\mathbf{d}} + \hat{\mathbf{n}})$ represents the axis of maximum tension and the direction of maximum positive amplitude of P waves; it plots at the center of the shaded quadrants on the beachball. The direction $\mathbf{P} = \frac{1}{\sqrt{2}} (\hat{\mathbf{d}} - \hat{\mathbf{n}})$ is the axis of maximum compression (often and improperly called “pressure axis”) and that of maximum negative amplitude of P waves; it plots at the center of the open quadrants. The direction $\mathbf{B} = \hat{\mathbf{d}} \times \hat{\mathbf{n}} = \mathbf{T} \times \mathbf{P}$ is the hinge of the fault planes; it is a direction where both P and S amplitudes vanish. For a given beachball, the $\mathbf{T}$, $\mathbf{P}$, $\mathbf{B}$ axes are independent of the choice between the two possible fault planes.

The interpretation of focal mechanisms in terms of stress release is particularly suited to the study of intraplate

earthquakes, which express the release of stresses accumulated inside the plates by tectonic forces, while interplate events, which are controlled by the relative displacements of two of the Earth's plates at a common boundary, are more readily interpreted in terms of a slip vector on a fault plane.

Fundamental Results

The most important application of focal mechanisms was the verification of the fundamental concepts of continental drift, seafloor spreading, and plate tectonics, in the mid-1960s. These ideas were derived using the spatial distribution of earthquake epicenters but without the knowledge of the geometries of their ruptures. The latter could then be used as an independent verification of the concepts, following the development of the beachball model, and the deployment of the World-Wide Standardized Seismograph Network in the early 1960s. Sykes (1967) and Isacks et al. (1968) achieved a remarkable endorsement of the mechanisms predicted by plate motions (normal faulting expressing extension at the mid-oceanic ridges, underthrusting expressing convergence at the subduction zones), and most spectacularly, verified the polarity of strike-slip faulting at the oceanic transform faults, thus upholding the concept proposed by Wilson (1965).

Focal mechanisms inside subducting slabs were compiled by Isacks and Molnar (1971), who documented a universal mechanism of down-dip compression for events deeper than 450 km, expressing the difficulty of penetration by the slab of the lower mantle at the bottom of the transition zone. By contrast, a wide diversity of mechanisms is found in the upper parts of the slabs, where local parameters such as rate and steepness of subduction, as well as possible bending stresses, control the stress field accumulated inside the slab during the subduction process.

A most remarkable aspect of the focal mechanisms of deep earthquakes is the fact that, without exception, they can be modeled by a double-couple (e.g., using its beachball representation), even though the concept of brittle rupture should not apply at the relevant pressure and temperature conditions inside the slabs. In particular, modern analysis of major deep earthquakes (Kawakatsu 1991; Okal 1996) has ruled out the possibility of an isotropic (implosive) source even as a mere component of their mechanism, as initially envisioned by Bridgman (1945) and proposed by Gilbert and Dziewonski (1975). Deep events represent faulting on a planar dislocation in the framework of Fig. 1, and differ from their shallow counterparts only in their usually higher level of stress drop (Antolik et al. 1999), but not in the geometrical or mechanical nature of their process. This observation supports the hypothesis that deep earthquakes may be induced by transformational faulting in volumes of metastable olivine persisting

inside the slabs at greater depths than predicted by equilibrium thermodynamics (Kirby et al. 1996).

Modern Focal Solutions: Inversion of the Moment Tensor

The double-couple used to represent a seismic source can be used, through its components given by Eq. (1), as a forcing term in the wave equations expressing the fundamental law of dynamics (a variation of " $\mathbf{F} = m \mathbf{a}$ "), to compute simulations of the Earth's response in space and time to the seismic disturbance. These are known as *synthetic seismograms*.

Conversely, and since the 1970s, inversion techniques have been used to derive the individual components of earthquake moment tensors directly from the waveforms of their recorded seismograms. Essentially, a best-fitting algorithm is used to express a large dataset of observed seismograms as a linear combination of synthetic seismograms computed for each individual component of the moment tensor. In addition, and for sufficiently large datasets, the inversion can resolve the best location in space of the source, and its result is known as a "centroid moment tensor" or CMT. These techniques, which can be applied on body waves, surface waves, or normal modes, as well as on regional phases in the near field, can be carried out automatically on digital data, and eliminate the occasional difficulty of picking a first motion polarity under noisy or emergent conditions. They have replaced the compilation of *P*-wave first motions as the primary source of earthquake focal mechanisms.

In particular, the Global CMT (*ex*-Harvard CMT) project, described initially by Dziewonski et al. (1981), has now inverted more than 30,000 earthquake sources since 1976, through a uniform, comprehensive procedure, into a catalog that has become the backbone of most modern seismotectonic studies.

Evaluation Tools for Double-Couple Solutions

Because of the relative complexity of the double-couple source that cannot be represented by a vector, a number of applications have been developed to illustrate their properties in a user-friendly representation. Among them, Frohlich and Apperson (1992) have proposed to plot focal mechanisms in a ternary diagram whose apices are the "*pure*" mechanisms corresponding to vertical stress axes (**B**, strike-slip; **T**, thrust; or **P**, normal); using barycentric coordinates within the triangle, the position of the mechanism indicates at a glance the nature of faulting (Fig. 5). Note that it remains independent of the azimuth ϕ of the fault strike.

In order to help compare different earthquakes, Kagan (1991) has offered an algorithm to quantify the proximity of

Earthquake, Focal Mechanism, Fig. 5 Ternary representation of focal mechanisms (Frohlich and Apperson 1992). This approach uses barycentric coordinates with respect to end members with one vertical principal axis. Mechanisms close to apices are either predominantly strike-slip (SS), thrust (T) or normal (N). Hybrid mechanisms (H) plot in the center of the diagram. By contrast, the sides of the diagram represent geometries with one horizontal axis. This representation is useful when studying trends among large families of mechanisms, such as intraplate earthquakes, irrespective of their particular strike angles

two focal solutions given by their angles ($\phi_1, \delta_1, \lambda_1$) and ($\phi_2, \delta_2, \lambda_2$). It computes the angle ω of the minimum solid rotation bringing one of the beachballs onto the other. Because of their symmetry, the maximum value of ω is 120° .

Non-double-Couple Solutions

The double-couple is a four-dimensional mathematical entity which constitutes a subset (featuring a zero-eigenvalue) but not a sub-vector space, of the five-dimensional vector space of deviatoric (i.e., zero-trace), symmetric second-order tensors. Consequently, linear inversions are carried out in the full five-dimensional space. The quality of fit of the inverted solution to a double-couple is assessed through a so-called compensated linear vector dipole (CLVD) parameter ϵ , expressing the ratio of the intermediate eigenvalue of the moment tensor to its largest one (in absolute value). In principle, ϵ could range from -0.5 to 0.5 and should be 0 for a perfect double-couple. The average value of $|\epsilon|$ for the whole CMT catalog is 0.12 , which constitutes a good verification of the concept of the double-couple, especially since it falls to 0.08 for earthquakes with moments $M_0 \geq 10^{26}$ dyn cm. Occasionally, larger values of $|\epsilon|$ (which can reach 0.4) indicate a deviation from the model of a double-couple, which may result from a number of scenarios. For example, earthquakes with complex ruptures consisting of multiple events with differing geometries will feature an overall deviatoric moment tensor, which however

cannot be described in terms of a lone double-couple. A recent example is the Samoa event of 29 September 2009 ($M_0 \approx 1.8 \times 10^{28}$ dyn cm; $\epsilon = 0.37$), which was modeled as a main outer rise normal faulting event triggering a smaller underthrusting shock on the nearby interplate contact (Li et al. 2009).

Other examples of non-double-couple solutions would include dyke injections during volcanic events (e.g., Tori-Shima Volcano, 13 June 1984; $\epsilon = 0.33$; Kanamori et al. 1993), rupture on nonplanar faults, again in a volcanic environment (Ekström 1994), and certain cryoseismic events believed to involve calving at the front of glaciers (e.g., 15 August 2008, $\epsilon = 0.33$; Nettles and Ekström 2009).

Conclusion

Focal mechanisms provide a mathematical or illustrative representation of the geometry of the rupture process during an earthquake. Their compilation forms the basis of our interpretation of earthquakes in the framework of global tectonics.

Earthquake, Foreshocks

Mian Liu

Preshocks

Definition

Foreshocks. Smaller earthquakes preceding a large earthquake (the mainshock) in an earthquake sequence.

Introduction

Earthquakes typically occur in sequences that may include foreshocks, the mainshock (the largest event or events), and aftershock (► “[Earthquake, Aftershocks](#)”). Earthquake sequences without a clear mainshock are called swarms.

Foreshocks are the most obvious premonitory phenomenon of earthquakes. They are thought to indicate earthquake nucleation and hence may have the potential for short-term earthquake prediction (Scholz 2002). However, proof of the physical link between foreshocks and earthquake nucleation

is inconclusive, and earthquake prediction using foreshocks has not been reliable.

The problem begins with their recognition – foreshocks are earthquakes that are called foreshocks retrospectively, when a large event (the mainshock) followed. To be considered as foreshocks, these events need to occur within certain spatial and temporal windows, and need to be distinguished from background seismicity. Such spatiotemporal windows vary in different studies, and selecting foreshock events can be difficult, depending on the completeness of the earthquake catalogs available and other factors (Mignan 2014). Foreshocks are typically located within the mainshock’s source area with a dimension roughly the length of the fault rupture, which is in the order of 50–100 km for a magnitude 7.0 earthquake. Temporally, most foreshocks occur a few days to hours before the mainshock (Jones and Molnar 1979). In some cases, seismicity increases a few months or years before the mainshock. Some workers consider such increased seismicity foreshocks, others do not (Scholz 2002). Various studies suggest that 10–70% of large earthquakes may be preceded by foreshocks (Abercrombie and Mori 1996; Chen and Shearer 2016; Jones and Molnar 1979). A recent study found higher percentage of mainshocks associated with foreshock activity, using a high-resolution catalog in southern California that includes much more events, mostly small ones ($-2 < M < 0$), than previous catalogs (Trugman and Ross 2019). While the percentage varies with different studies and in different regions, it is important to note that not all earthquakes are preceded by foreshocks.

Characteristics of Foreshocks

Foreshocks, when they do occur, are typically few in comparison with aftershocks, sometimes consisting of only a few or a single event, hence are difficult for quantitative analysis. When considered collectively, they are shown to exhibit a temporal pattern similar to that of aftershocks (Jones and Molnar 1979; Shaw 1993). Most foreshocks occur within 10 days before the mainshock, and their numbers accelerate till the occurrence of the mainshock. The collective time sequence of foreshocks seems to fit an inverse Omori’s law:

$n(t) = at^{-q}$ where $n(t)$ is the number of foreshocks by time t before the origin of the mainshock, and a and q are constants, with q close to 1 (Kagan and Knopoff 1978; Papazachos 1975). Thus, the number of foreshocks tends to increase hyperbolically as time approaches the origin of the mainshock. Some studies suggest that foreshocks may have lower b -values (see entry ► “[Earthquake, Aftershocks](#)”) relative to aftershock sequences and background seismicity (Scholz 2002; Utsu 1966).

It is not clear why some earthquakes have foreshocks while others do not. Studies of global and regional earthquake catalogs have found that neither the time sequences nor the largest

magnitude of foreshocks correlate to the magnitude of the mainshock (Jones and Molnar 1979), suggesting either the size of the mainshock is independent of the earthquake nucleation process, or foreshocks are not part of earthquake nucleation (Abercrombie and Mori 1996). The incidence of foreshocks is found to be higher for shallower mainshocks and regions of higher heat flow (Abercrombie and Mori 1996; Chen and Shearer 2016; Trugman and Ross 2019). These results may suggest that foreshocks are related to small-scale heterogeneities in Earth's crust (Abercrombie and Mori 1996).

Causes of Foreshocks

The causes of foreshocks remain uncertain. Many workers view foreshocks as events related to earthquake nucleation. Evidence favoring this view includes laboratory experiments, which commonly show precursory slip events analogous to foreshocks (Bolton et al. 2019; Johnson et al. 2013). Theoretically, fault ruptures only when slip has occurred over a fault patch of some critical radius. Ohnaka (1992) has proposed a theoretical model that attributes the generation of foreshock to failure of asperities loaded by accelerating premonitory creep. This model predicts numerous features found in foreshocks: their occurrence typically a few days before the mainshock, their accelerated rates as time approaches that of the mainshock, and their occurrence in the immediate vicinity of the hypocenter of the mainshock. Some earthquake sequences in California show evidence of nucleation (Dodge et al. 1995). However, not all foreshocks readily fit the nucleation model. Aside from the obvious problem that many earthquakes do not have foreshocks, the nucleation model has difficulties explaining foreshocks that occur away from the rupture plane or have significantly different focal mechanisms from that of the mainshock (Jones et al. 1982).

Others think that foreshocks are fundamentally the same as other earthquakes (Felzer et al. 2004; Helmstetter et al. 2003). In this view, foreshocks, the mainshock, and aftershocks are just different names for earthquakes within the same sequence of cascading ruptures triggered by a common mechanism. The progression of a series of foreshock ruptures towards the mainshock hypocenter of the 1999 Izmit earthquake (Mw 7.6) in Turkey supports this view (Ellsworth and Bulut 2018).

Can Foreshocks Be Used to Predict Earthquakes?

Foreshocks are the most obvious precursor of earthquakes. If they are associated with earthquake nucleation, then they are potentially useful for short-term earthquake prediction. The best example is perhaps the 1975 Haicheng earthquake (magnitude 7.3) in China, which was predicted largely based on foreshocks, more than 500 of which were recorded within

4 days before the mainshock (Jones et al. 1982). However, an investigation by Wang et al. (2006) has revealed that the role of foreshocks in this prediction was more psychological than scientific: the jolts and damages from increased seismicity in the preceding months stressed people's minds, and the intensified foreshocks in the last day before the mainshock prompted some local officials to order an evacuation. In other places where official orders were not issued, the increased seismicity caused many residents to evacuate voluntarily.

Aside from the problem that many earthquakes do not have foreshocks, short-term earthquake prediction using foreshocks is challenging in theory and in practice. Even if foreshocks are physically linked to the process leading to the mainshock, the complexity of the linking processes in nature means that foreshocks probably will not help much for short-term earthquake prediction. On the other hand, if foreshocks are fundamentally the same as other earthquakes (Felzer et al. 2004; Helmstetter et al. 2003), then foreshocks cannot be predictors of mainshocks. In practice, we have yet to find any reliable ways to recognize foreshocks from background seismicity before the occurrence of the mainshock.

Nonetheless, there must be some symptoms associated with the stress buildup and physical property changes in and around the fault leading to a major rupture, and foreshocks are the most obvious symptoms known to us. Further studies of foreshocks will improve our understanding of the mechanics of earthquakes. There is increasing evidence of various creep slips before a mainshock (McGuire et al. 2005; Tape et al. 2018). On the other hand, by treating every earthquake as a potential foreshock that may be followed by a mainshock, statistical models based on the clustering properties of earthquake sequences can be developed to assess the real-time probability of damaging earthquakes, as has been done in California (Field et al. 2016; Gerstenberger et al. 2005; Jones 1985; Reasenber and Jones 1989).

Summary

Foreshocks are smaller earthquakes preceding a mainshock. They are thought to manifest the nucleation of the mainshock, hence have the potential for short-term earthquake prediction. However, not all large earthquakes are preceded by foreshocks, and they are difficult to recognize from the background seismicity before the occurrence of the mainshock. Foreshocks may also be fundamentally the same as other earthquakes, if so they cannot be used as earthquake predictors.

Earthquake, Magnitude

Peter Borman
(Deceased)

Synonyms

Richter scale

Definition

The *magnitude* of an earthquake is a number that characterizes the relative size or amount of elastic energy released by such an event (see ► [“Earthquakes, Energy”](#)). It is usually based on measurement of the maximum ground motion recorded by a seismograph (sometimes for a particular wave type and frequency) and corrected for the decay of amplitudes with epicentral distance and source depth due to geometric spreading and attenuation during wave propagation (see ► [“Propagation of Elastic Waves: Fundamentals”](#)).

Original Definition of Earthquake Magnitude

The first paper on earthquake magnitude was published by Charles F. Richter (1935), titled *An instrumental earthquake magnitude scale*. Therefore, often reference is made to the size or strength of earthquakes as measured on the *Richter scale*. Yet, this may be incorrect, especially for large earthquakes (magnitude saturation). Richter (1935, p. 1) wrote: “In the course of historical or statistical study of earthquakes in any given region it is frequently desirable to have a scale for rating these shocks in terms of their original energy, independently of the effects which may be produced at any particular point of observation.” The term *magnitude* scale was recommended to Richter by H.O. Wood in distinction to the name *intensity* scale (see ► [“Earthquakes, Intensity”](#)), which classifies the severity of earthquakes mainly on the basis of felt shaking or damage manifestations at different localities.

Richter compared records of a standard type of short-period horizontal component Wood-Anderson (WA) torsion

Earthquake, Magnitude, Fig. 1 Normalized amplitude– frequency responses of standard types of seismographs (or of their simulation filters) required for measuring several common types of magnitudes in agreement with recent IASPEI (2005) recommendations: Wood-Anderson seismograph and the short-estimated via the arrival period (SP) and long-period (LP) seismographs used in the former US World-Wide Standard Seismograph Network (WWSSN) (Seismic Instrumentation). (Reprint from IASPEI 2005. With copyright granted by IASPEI)

seismograph at different distances and azimuths from the earthquake source. All seismographs had an identical frequency response (red curve in Fig. 1) and a static magnification of (said to be) 2800. Many stations in Southern California were equipped with WA seismometers. Figure 2 shows a typical record of a near earthquake. Plotting for each event the logarithm of the recorded maximum trace amplitudes $A_{\max}$ over the epicentral distance Δ (see ► “Earthquakes, Location Techniques”) Richter derived an average attenuation law for a reference amplitude A_0 up to agreement with the above original definition $\Delta = 600$ km. He then corrected amplitudes measured at different stations by the $-\log A_0(\Delta)$ values. Thus measured amplitudes became comparable for a given event and differences of corrected amplitudes for different events indicative for difference in event size. In conclusion Richter (1935, p. 31) states:

The magnitude of a shock is defined as the logarithm of the calculated maximum trace amplitude, expressed in microns, with which the standard short-period torsion seismometer ($T_0 = 0.8$, $V = 2,800$, $h = 0.8$) would register that shock at an epicentral distance of 100 km.

Since then several other magnitude scales have been developed. They are based on different types of seismic waves (Bormann et al. 2002a; ► “Body Waves” and ► “Surface Waves”), recorded by seismographs with different frequency responses (e.g., those shown in Fig. 1) and measured at

Earthquake, Magnitude, Fig. 2 Record of a short-period Wood-Anderson seismograph of a local earthquake. P marks the onset of the first arriving longitudinal wave, and S that of the shear wave. Note the long tail of scattered coda-waves following S. From the time difference $S - P = 24$ s follows a distance of about 190 km. The largest amplitude is $A_{\max} = 23$ mm. With $-\log A_0(190 \text{ km}) = 3.45$ (Richter 1958) Eq. 1 yields $M_L = 4.8$. (Modified from Fig. 1 in Bormann and Saul 2009a. With copyright granted by Springer)

different periods and source distances. Yet, all had to be mutually scaled so that at certain magnitudes they yield values in agreement with the above original definition.

Local Magnitude Scales

The *Richter scale* is termed M_L and applicable only to earthquakes recorded at local to near regional distances, typically less than 1,000 km distance. Its formula reads:

$$M_L = \log_{10} A_{\max} - \log A_0(\Delta). \quad (1)$$

Figure 2 shows how the trace amplitude $A_{\max}$ on a WA record is measured and the distance Δ estimated via the arrival-time difference between the P- and S-waves. Figure 3 is a compilation of different $-\log A_0(\Delta)$ calibration curves for different seismotectonic regions of the world. The Richter values for Southern California form the dot-step curve. Tabulated Richter values and calibration formulas for the other curves are given by Bormann (2002).

Figure 3 illustrates that M_L calibration functions may strongly differ from region to region because of differences in crustal structure, thickness, age, heat flow and related wave propagation and attenuation properties. Therefore, in order to assure compatibility of M_L values measured in different regions one has to (a) investigate the regional amplitude-attenuation conditions, (b) derive regional calibration functions, and (c) scale them so as to yield for identical amplitudes measured at 100 km *epicentral* distance the same M_L as with the Richter $-\log A_0(\Delta)$ value at this distance. However, in order to assure a better comparison of earthquakes in regions having very different attenuation of waves within the first 100 km, Hutton and Boore (1987) recommend to define local scales such that $M_L = 3$ corresponds to 10 mm trace

Earthquake, Magnitude,
Fig. 3 Calibration functions for M_L determination in different regions. (Reprint of Fig. 3.12 in Bormann et al. 2002b. With copyright granted by IASPEI)

amplitude on a Wood-Anderson instrument at 17 km *hypo-central* distance rather than 1 mm at 100 km *epicentral* distance. Further, empirical measurements proved that the static magnification of the WA seismographs is not 2,800 but around $2,080 \pm 60$ (Uhrhammer and Collins 1990).

Moreover, gain and response of modern seismographs may differ significantly from those of WA seismographs. Therefore, the Working Group on Magnitude Measurements of the International Association of Seismology and Physics of the Earth's Interior (IASPEI 2005) recommends for crustal earthquakes in regions with attenuative properties similar to those of Southern California the following standard formula:

$$M_L = \log_{10} A_{\max} + 1.11 \log_{10} R + 0.00189 * R - 2.09 \quad (2)$$

where $A_{\max}$ = maximum trace amplitude in nm that is measured on the output from a horizontal-component instrument that is filtered so that the response of the seismograph/filter system replicates that of a Wood-Anderson standard seismograph but with a static magnification of 1, and R = hypocentral distance in km, typically less than 1,000 km.

For crustal earthquakes in regions with different attenuative properties and for measuring magnitudes with vertical-component seismographs, the standard equation is of the form:

$$M_L = \log_{10}(A_{\max}) + C(R) + D \quad (3)$$

where $A_{\max}$ and R are defined as in Eq. 2, except that A may be measured from a vertical-component instrument, and where $C(R)$ and D have been calibrated to adjust for the different regional attenuation and for any systematic differences

between amplitudes measured on vertical instead of horizontal components. Besides M_L scales that measure $A_{\max}$, typically of relatively weak motion, also M_L^{SM} scales have been developed, which are based on peak ground accelerations (e.g., Lee et al. 1990; Hatzidimitriou et al. 1993; *Earthquakes, Strong-Ground Motion*). Also the duration d of the event record or of its coda length c after the S onset can be used for estimating magnitude from locally recorded data (Bormann et al. 2002b). Further, there exist regression relationships which relate magnitude values to other observed parameter data such as (see ► “Earthquakes, Intensity”). But any such alternative local scale has to be developed individually for different seismic networks or regions because of regionally variable attenuation, scattering, signal-to-noise and other conditions. Also, for assuring the compatibility of their values these scales should be calibrated with amplitude-based M_L .

Teleseismic Magnitude Scales

Surface-Wave Magnitudes

Beno Gutenberg modified the Richter scale for application in the teleseismic range ($\Delta \geq 20^\circ$; $1^\circ = 111.22$ km) by using both body and surface waves. For shallow earthquakes the latter have by far the largest amplitudes in seismic records (Fig. 4). The Gutenberg (1945a) formula for surface wave magnitude is

$$M_s = \log A_{H\max} + 1.656 \log \Delta + 1.818 \quad (4)$$

with $A_{H\max}$ = vectorially combined maximum horizontal surface-waves displacement amplitude in micrometer

Earthquake, Magnitude, Fig. 4 Amplitude decay with distance for short-period (1 Hz) P- and PKP-waves as well as long-period (≈ 20 s) Rayleigh surface waves LR radiated by an earthquake of magnitude 4. (Reprint of Fig. 3.13 in Bormann et al. 2002a. With copyright granted by IASPEI)

measured at periods T around 20 s and the term $1.656 \log \Delta$ which compensates for the amplitude decay with distance in the range $20^\circ \leq \Delta < 140^\circ$. Equation 4 is best scaled for surface waves with oceanic travel paths.

Later, a group of Czech and Russian seismologists investigated the propagation of surface waves with dominantly continental travel paths, using records of seismographs of type Kirnos that are proportional to ground displacement in a wide range of periods. They found that surface waves may have their largest amplitudes in a much wider range of periods between about 3 and 30 s, as confirmed by Bormann et al. (2009); (see Fig. 5). Moreover, estimates of M_s proved to be more stable in a wider range of epicentral distances between 2° and 160° if one measures instead of $A_{\max}$ the ratio $(A/T)_{\max}$ (Vaněk et al. 1962). This ratio relates to ground velocity $V_{\max} = 2p(A/T)_{\max}$ and thus to the energy contained in the respective wave group. Therefore, these authors proposed a modified M_s formula, which is IASPEI standard for M_s determination since 1967:

$$M_s = \log (A/T)_{\max} + 1.66 \log \Delta + 3.3. \quad (5)$$

National and global seismic networks and data centers run or initiated by the USA accepted Eq. 5. However, with the introduction of the WWSSN they did not avail of medium- to long-period broadband displacement records that were standard equipment at first-rate stations over most of the Eurasian territory. Also, they continued to measure $A_{\max}$ only at periods around 20 s rather than true $(A/T)_{\max}$ in the whole surface-wave train. But then the use of Eq. 5 results in significantly distance-dependent M_s estimates (see discussion in Bormann

Earthquake, Magnitude, Fig. 5 Variability with distance Δ of periods associated with $(A/T)_{\max}$ in vertical component surface waves records. The gray shaded stripe marks the period range between 18 and 22 s, the light-gray columns mark the observed range of average periods as published by Vaněk et al. (1962), and the stars the average periods for different increments of the data cloud. (Reprint of Fig. 8 by Bormann et al. 2009, p. 1874. With copyright granted by the Seismological Society of America)

et al. 2009). Proposed new calibration functions for 20 s surface-waves, e.g., by von Seggern (1977), Herak and Herak (1993) and Rezapour and Pearce (1998) have not yet been accepted as global standards. In contrast, Kirnos-based M_s measurements in accordance with formula 5 have ever since been carried out in the former Soviet Union and its allied countries, in the now Commonwealth of Independent States (CIS), and China.

Thus, two traditions of M_s measurements have been practiced for half a century, producing a host of valuable but not fully compatible data. Yet, the generic nomenclature M_s does not allow to discriminate between these two kinds of data. Moreover, M_s is measured by different agencies still in sometimes different ranges of source-depth, on different record components of different types of seismographs and sometimes even using different calibration functions, e.g., the International Data Centre (IDC) of the Comprehensive Test-Ban Treaty Organization (see ► “Seismology, Monitoring of CTBT”). This may result in procedure-dependent errors that have to be reduced by standardization of both nomenclature and procedures. This task is eased by the fact that modern digital broadband records allow to accurately synthesize records of classical seismographs, on which the original definition of magnitude scales often rests. Moreover, modern broadband records are mostly proportional to velocity and allow to measure $(A/T)_{\max}$ directly and unambiguously on unfiltered traces. Therefore, IASPEI (2005) recommends for shallow earthquakes with source depth $h < 60$ km in future two surface-wave magnitude standards, namely, (a) a purely teleseismic one in the range $20^\circ \leq \Delta \leq 160^\circ$, termed $M_s(20)$, or when written in the International Seismological Format (ISF):

$$M_{S_20} = \log_{10}(A/T) + 1.66 \log_{10}\Delta + 0.3 \quad (6)$$

where A = vertical-component ground displacement in nanometer measured from the maximum surface-wave trace-amplitude having a period between 18 and 22 s on a waveform that has been filtered so as to replicate the record of the WWSSN-LP seismograph (Fig. 1), and (b) another broadband (BB) surface-wave magnitude that is measured in a wider distance range of $2^\circ \leq \Delta \leq 160^\circ$, termed $M_s(BB)$, or in the ISF format:

$$M_{s_BB} = \log_{10}(A/T)_{\max} + 1.66 \log_{10}\Delta + 0.3 \quad (7)$$

where $(A/T)_{\max} = (V_{\max}/2\pi)$, with $V_{\max}$ = ground velocity in nm/s associated with the maximum trace-amplitude in the surface-wave train recorded on a vertical-component seismogram that is proportional to velocity, and where the period T is between $3 \text{ s} < T < 60 \text{ s}$. $M_s(BB)$ generally agrees well with $M_s(20)$, however, for weaker regional and local earthquakes it may yield up to about 0.5 magnitude units (m.u.) larger values than $M_s(20)$ (Bormann et al. 2009). Besides these two standard M_s there exist other surface-wave magnitude scales. E.g., Bonner et al. (2006) proposed a largely theory-based $M_s(V_{\max})$ that requires multi-bandpass filtering and frequency-dependent attenuation corrections. Another scale, termed Mm (Okal and Talandier 1989), uses very long-period

surface-wave amplitudes with periods between 60 and 400 s, which penetrate into the earth mantle. Mm does not saturate (magnitude saturation) and thus is well suited for tsunami warning (e.g., Weinstein and Okal 2005).

Body-Wave Magnitudes

Gutenberg (1945b, c) teleseismic magnitude scales for body-waves are applicable also to deep earthquakes down to source depths $h \approx 700 \text{ km}$. Diagrams and tables with calibration values $Q(\Delta, h)$ for P, PP, and S waves (see ► “Seismogram Interpretation”), covering the distance range between about 5° and 170° , were published by Gutenberg and Richter (1956) (see also Bormann 2002). Figure 6 shows the Q -values for vertical component P waves. It is the only classical body-wave scale which is still widely used. The general body-wave magnitude formula, applicable in the range $20^\circ \leq \Delta \leq 100^\circ$ reads, when A is measured in micrometer:

$$m_B = \log_{10}(A/T)_{\max} + Q(\Delta, h). \quad (8)$$

Gutenberg derived the Q -functions by analyzing mostly medium- to long-period body-wave amplitudes with periods $2 \text{ s} < T < 30 \text{ s}$ (Abe 1981). Therefore he did not account for frequency-dependent attenuation. Yet, the latter becomes significant for P-waves with $T < 4 \text{ s}$ (Di Giacomo et al. 2008). Further, Gutenberg measured $(A/T)_{\max}$ within the whole

Earthquake, Magnitude, Fig. 6 Calibration values $Q(\Delta, h)$ for vertical (Z) component P-wave amplitudes as a function of epicentral distance Δ in degree and source depth h in kilometer. They are used for the

calculation of body-wave magnitudes m_B and m_b . (Figure redrawn from Gutenberg and Richter 1956. Reprint of Fig. 1a in Bormann 2002. With copyright granted by IASPEI)

P-wave train and not within a fixed short time window after the P-wave onset. This was not taken into account when introducing with the WWSSN in the 1960s a short-period P-wave magnitude m_b . It measured $A_{\max}$ on narrow-band WWSSN-SP records (Fig. 1) at periods < 3 s (mostly around 1 s) at fixed time-windows. The main advantage was the improved signal-to-noise ratio. It allowed teleseismic magnitudes to be determined down to $m_b \approx 4$. m_b became standard in all western countries, which discontinued to measure m_B . Yet, on average for values above 5.5, m_b tends to be smaller than other kinds of magnitudes (see Fig. 7). Reasons are discussed in the section on “Magnitude “Saturation””.

Measurement procedures for m_b have been rather inconsistent, using different frequency responses, measuring the amplitudes within different time windows, applying different calibration functions (e.g., the IDC). The detrimental effect of such inconsistencies became strikingly evident after the great $M_w 9.3$ Sumatra earthquake of 26 December 2004. The IDC reported $m_b = 5.7$, CENC 6.3, NEIC 7.0 and the German Regional Seismic Network (GRSN) 7.5. The IDC and CENC measured $A_{\max}$ within 5 s, the NEIC within 60 s, and the GRSN some 90 s after the first P onset. Such differences for the same event on a logarithmic scale are not tolerable and necessitate standardization of procedures. Broadband $m_B = 8.3$ was still larger than the largest m_b value.

Based on such experience IASPEI (2005) proposes two complementary teleseismic body-wave magnitude standards:

$$m_b = \log_{10}(A/T) + Q(\Delta, h) - 3.0 \quad (9)$$

where: A = P-wave ground amplitude in nm, calculated from the maximum trace-amplitude in the entire P-phase train (time spanned by P, pP, sP, possibly PcP and their codas, and ending preferably before PP; *Seismogram Interpretation*); period $T < 3$ s, Δ in the range $20^\circ \leq \Delta \leq 100^\circ$ and h between 0 and 700 km. T and A are measured on the output of a vertical-component instrument that is filtered so that the frequency response of the seismograph/filter system replicates that of a WWSSNSP seismograph (Fig. 1). This new definition of m_b yields for great earthquakes significantly larger values than common procedures. None the less, short-period m_b should – at least for $m_b > 5.5$ – be complemented by broadband $m_B(BB)$, which reads in ISF format:

$$m_{B-BB} = \log_{10}(A/T)_{\max} + Q(\Delta, h) - 3.0, \quad (10)$$

where: $(A/T)_{\max} = (V_{\max}/2p)$, with $V_{\max}$ = ground velocity in nm/s associated with the maximum trace-amplitude in the entire P-phase train (see m_b) as recorded on a vertical-component seismogram that is proportional to velocity at least in the period-range $0.2 \text{ s} < T < 30 \text{ s}$; $Q(\Delta, h)$, Δ and h ranges are as for m_b .

Besides these two body-wave standards there exist several other broadband P-wave magnitudes. Most of them aim at fast estimates of the moment magnitude M_w (non-saturating magnitude scales).

Relationships Between Magnitude Scales and Released Seismic Energy E_s

There is no “true” single magnitude parameter which can be sufficiently reliable and completely characterize both size and shaking strength of earthquakes and thus related *Seismic hazard*. Depending on the measured kinematic parameters and their frequency range the magnitudes relate to different geometric, kinematic, or dynamic aspects of the (see ► “Earthquake Rupture: The Inverse Problem”). Accordingly, the scales discussed so far do not scale 1:1, agree in some value ranges but differ in others. Although Fig. 7 hints to sometimes nonlinear relationships, the most important ones are reasonably linear within the range of data scatter, e.g., that of Gutenberg and Richter (1956).

$$m_B = 0.63M_s + 2.5. \quad (11)$$

Equation 11 is well reproduced by the new standards $m_B(BB)$ and $M_s(BB)$ (Bormann et al. 2009) but differs strongly from the $m_b - M_s(20)$ relationship (Gordon 1971):

$$m_b = 0.47M_s(20) + 2.79. \quad (12)$$

Despite the shortcomings of narrow-band m_b and $M_s(20)$ they are particularly useful for discriminating earthquakes and Nuclear Explosions.

Earthquake, Magnitude, Fig. 7 Average relationships of different common types of magnitude scales with the moment magnitude M_w (non-saturating magnitude scales). M_{JMA} is determined by the Japanese Meteorological Agency. (Modified from Fig. 1 of Utsu (2002). Reproduction of Fig. 4 in Bormann and Saul (2009a). With copyright granted by Springer)

Gutenberg and Richter (1956) published also a semiempirical relationship between m_B and seismic energy E_s :

$$\log E_s = 2.4m_B - 1.2 \text{ (with } E_s \text{ in units of Joule)}. \quad (13)$$

When inserting Eqs. 11 into 13 one gets

$$\log E_s = 1.5M_s + 4.8. \quad (14)$$

M_s in all these formulas means $M_s(20)$. But, 20 s displacement amplitudes are not very representative for the radiated seismic energy, especially not for smaller earthquakes. Another relationship has been derived by Kanamori et al. (1993) between M_L and $\log E_s$ for Southern California, valid in the range $1.5 < M_L < 6.0$:

$$\log E_s = 1.96M_L + 2.05. \quad (15)$$

But any such relationship allows only rough estimates of E_s within about an order of magnitude. This uncertainty can nowadays be reduced, down to a factor of about 3–5, by integrating squared velocity broadband records with good signal-to-noise ratio in the teleseismic range and thus measuring directly (see ► “Earthquakes, Energy”).

Magnitude “Saturation”

Magnitude saturation is a widely but not uniquely used term in seismological literature. Originally, one assumed that classical magnitudes do not increase further beyond some value of a reference magnitude of earthquake size such as M_w (non-saturating magnitude scales) (e.g., Geller 1976; Kanamori 1983). However, such a complete saturation is not supported by Figs. 7 and 8 and recently published data (e.g., Bormann et al. 2009). We therefore may speak of magnitude “saturation,” or more correct underestimation of earthquake size, also if one magnitude M_x increases slowly with respect to increases in M_w (see Fig. 7). Such saturation may occur when the earthquake rupture duration is much longer than the periods at which $A_{\max}$ or $(A/T)_{\max}$ are measured.

This is also illustrated by Fig. 8, calculated for a common ω^{-2} source model (Aki 1967), assuming an average rupture velocity, stress drop in the source volume and ratio E_s/M_0 . For details see Bormann et al. (2009). The spectra have been plotted together with the periods, respectively period ranges, at which m_b , $m_B(BB)$, $M_s(20)$ and $M_s(BB)$ are measured. The left panel is scaled to $M_0 = \mu D F$ (where F = rupture area, D = average displacement over the fault and μ = average rigidity of the rock material in the source volume) and the right panel to the time derivative of M_0 (moment rate), which is proportional to far-field ground motion velocity. M_0 can only be estimated correctly when displacement amplitudes are

measured at frequencies less than the corner frequency f_c (left panel) and seismic energy, which is proportional to the squared ground motion velocity, only when velocity spectral amplitudes are measured sufficiently wide around f_c . Accordingly, m_b measured around 1 Hz necessarily begins (on average) to underestimate both M_0 and E_s for $M_w > 5$ to 5.5, in contrast to the broadband magnitudes, which are more closely related to M_0 and E_s up to M_w 7.5–8. The spectral reasons for underestimating earthquake size or energy release may be aggravated by too short a measurement time window, which was rather common for m_b . Figure 9 illustrates both the spectral and timewindow component of magnitude saturation.

Non-Saturating Magnitude Scales

Kanamori (1977), Purcaru and Berckhemer (1978) and Hanks and Kanamori (1979) proposed a non-saturating magnitude scale for very large earthquakes, based on M_0 data. Kanamori termed it M_w . For converting M_0 into M_w Kanamori (1977) replaced in Eq. 14 M_s by M_w and assumed an average ratio $E_s/M_0 = 5 \times 10^{-5} = \text{constant}$. This led to a relationship, which reads in the IASPEI (2005) recommended standard form with M_0 in units of Nm:

$$M_w = (2/3)(\log_{10} M_0 - 9.1). \quad (16)$$

M_0 calculations are nowadays routine at major seismological centers, either by measuring the displacement amplitude u_0 on the long-period asymptote (plateau) of the wave spectrum, which is proportional to M_0 after correcting for the source radiation and wave propagation effects (as done in Fig. 8), or by fitting long-period synthetic seismograms for different source models best to long-period filtered real seismic records, using wavelengths that are larger than the rupture length (Dziewonski et al. 1981). However, if this condition is not fulfilled, as sometimes in routine computations, then also M_w may be underestimated, e.g., for the great 2004 Sumatra earthquake values between 8.2 and 9.3 were reported. The last value resulted from using either extremely long-period free oscillation data (Stein and Okal 2005) or from multiple CMT source analysis (Tsai et al. 2005). For all major earthquakes with $M_w > 5.5$ the Global Centroid Moment Tensor (GCMT) project publishes moment tensor and M_w solutions usually within a few hours after the event (<http://www.globalcmt.org/CMTsearch.html>). Regional centers, such as the Swiss Earthquake Service, may provide – with larger time delay – such data down to $M_w \approx 3.0$ when dense quality networks close to the source are available (Braunmiller et al. 2002).

Besides calculation of M_w via direct measurements of M_0 there exist several methods of fast M_w proxy estimates, e.g., M_{wp} in the context of tsunami early warning (Tsuboi et al. 1999). M_{wp} scales nearly 1:1 with broadband m_B (Bormann

Earthquake, Magnitude, Fig. 8 “Source spectra” of ground displacement amplitudes A for an “average” seismic shear source as a function of frequency f , scaled to M_0 and M_w . *Right*: The same as left, but for ground motion velocity amplitudes V , scaled to seismic moment rate and M_w . The maximum of seismic energy $E_s \sim V^2$ is radiated around f_c . The open arrows point to the center frequencies on the abscissa at which m_b and

$M_s(20)$ are measured. The horizontal bars mark the frequency range within which $V_{\max}$ of P- and Rayleigh-waves for $mB(BB)$ and $M_s(BB)$ should be measured. (Courtesy of Di Giacomo. Reproduced from Fig. 1 of Bormann et al. 2009, p. 1870. With copyright granted by the Seismological Society of America)

and Saul 2009a) but also tends to underestimate very great and (see ► “Slow Earthquake”). More advanced fast and non-saturating versions of broadband P-wave magnitudes are M_{wpd} by Lomax and Michelini (2009), the (unspecified) M by Hara (2007), and m_{Bc} , a modified “cumulative” m_B procedure for great multiple-rupture earthquakes (Bormann and Saul 2009b). All these procedures account additionally for rupture duration, estimated in real time. Another very perspective promising new method for rapid non-saturating moment tensor and M_w estimates uses very long-period W-phase observations between the P-wave and S-wave arrivals (Kanamori and Rivera 2008).

However, both M_0 and M_w are only long-period or quasi-static measures of earthquake size and thus of the tectonic earthquake effect. More relevant for assessing seismic hazard

in terms of the earthquake potential for causing shaking damage are estimates of the amount of released seismic energy E_s and of the corner frequency f_c . These two parameters largely control the relative amount of radiated high-frequency velocity amplitudes. This necessitates, complementary M_w , also an energy-scaled magnitude M_e , which better relates to the kinematics and dynamics of the earthquake rupture, such as rupture velocity and stress drop. Velocity-broadband records allow nowadays to estimate (see ► “Earthquakes, Energy”) directly by integrating squared velocity amplitudes over a wide range of periods around the peak of the velocity spectrum (see Fig. 8) and correcting them for wave propagation effects. Comparing so determined E_s values for hundreds of shallow earthquakes with their NEIC M_s magnitudes in the range $5.5 < M_s < 8.5$ Choy and Boatwright (1995) found

Earthquake, Magnitude,

Fig. 9 Plot of vertical-component P-wave records of an $M_w 8.4$ Peru earthquake at station MTE at $\Delta = 83.4^\circ$. It illustrates the difference between broadband m_B and short-period m_b for large earthquakes. *Top trace*: m_b based on measuring $A_{\max}$ and the related period T from the simulated WWSSN_SP record. *Second trace*: Time derivative of the top trace for making $V_{\max} = 8 \mu\text{m/s}$ for m_b , comparable with $V_{\max} = 123 \mu\text{m/s}$ on the *bottom trace*. The latter yields $m_B = 8.2$, in contrast to IASPEI standard $m_b = 7.0$, or 6.4 , when $A_{\max}$ is measured within the first 5 s. (Copy of Fig. 1 in Bormann and Saul 2008, p. 699. With copyright granted by the Seismological Society of America)

$$\log E_s = 1.5M_s + 4.4. \quad (17)$$

Equation 17 differs from Eq. 14 that was used for deriving the M_w relationship 16 only in the constant. Replacing in Eq. 17 M_s by M_e and resolving it for M_e yields

$$M_e = (2/3)(\log E_s - 4.4). \quad (18)$$

Di Giacomo et al. (2010b) showed that their $M_e(\text{GFZ})$ and the related $M_w(\text{GCMT})$ agree on average in the range $5.5 < M_w < 9$ within 0.1 m.u., with a standard deviation $SD = 0.25$. The respective deviations between $M_w(\text{GCMT})$ and $M_e(\text{NEIC})$ are larger. The reason is that $M_e(\text{NEIC})$ is calculated from E_s values to which theoretically derived source mechanism corrections have been applied. In contrast, $M_e(\text{GFZ})$ follows the tradition of classical magnitudes with no such corrections made to measured $A_{\max}$ or $V_{\max}$. The pros and cons of such corrections and of their size under real Earth conditions of wave radiation and propagation are still a matter of debate and require further research.

M_e and M_w may differ for the same earthquakes up to about 1 m.u. This is mainly due to the fact that earthquake stress drop and the related ratio E_s/M_0 are not constant but may vary more than two to three orders. Examples of striking differences in M_e and M_w have been published, e.g., by Choy and Kirby (2004) and by Di Giacomo et al. (2010a). Suitable seismotectonic setting provided, $M_e \ll M_w$ may be indicative for high tsunamigenic potential, and vice versa, $M_e \gg M_w$ for high shaking damage potential (see also Fig. 11 and related discussion).

Relationship Between M_w , M_e , and Classical Magnitudes

Scordilis (2006) published global regression relationships, based on many thousands of NEIC and ISC (International Seismological Centre) m_b and M_s values, with M_w values of the US Geological Survey and of Harvard. First regression relationships between IASPEI standard magnitudes with non-saturating M_w , M_e , and m_{Bc} have been derived by Bormann and Saul (2008, 2009a, b) and by Bormann et al. (2009). From the classical magnitudes, M_s relates for strong earthquakes best with M_w , tends to be smaller, however, for $M_w < 6.2$ – 6.5 and > 7.8 – 8.5 (see Fig. 7; Scordilis 2006; Ekström and Dziewonski 1988). Yet, $M_s(\text{BB})$ reduces to half the systematic underestimation of M_w by $M_s(20)$ towards smaller magnitudes (Bormann et al. 2009). The $M_s(20)$ bias had been predicted already theoretically by Kanamori and Anderson (1975).

The first magnitude-energy Eq. 13 had been defined with m_B . Automatically determined $m_B(\text{GFZ})$, which agrees with IASPEI standard $m_B(\text{BB})$, correlates very well with $M_e(\text{GFZ})$ (Fig. 10), allowing estimates of M_e via simple m_B measurements with a $SD = \pm 0.18$ m.u. Both magnitudes are based on ground motion velocity and therefore reflect – when compared with M_w – in a similar way differences in source properties.

Figure 11 presents three records of equal M_w (within 0.1 m.u.), however very different rupture durations and m_B values. The Indian intra-plate Budj earthquake had the shortest rupture duration of about 30 s, the most impulsive waveform and largest $m_B = 8.2$, 0.6 m.u. larger than M_w .

This event caused tremendous shaking damage. In contrast, the two very slow Nicaragua and Java earthquakes with rupture durations around 200 s were (see ► [“Tsunami”](#)) earthquakes. Their m_B values were 0.5 and 0.7 m.u. smaller than M_w . Both earthquakes were not or only weakly felt at the relatively nearby coasts.

Earthquake, Magnitude, Fig. 10 Relationship between automatically determined values of m_B and M_e according to procedures developed at the GFZ German Research Centre for Geosciences by Bormann and Saul (2008) and Di Giacomo et al. (2010). The broken line is the 1:1 and the solid line the orthogonal regression relation $m_B = 0.79M_e + 1.58$. (Courtesy of D. Di Giacomo and J. Saul)

Earthquake, Magnitude, Fig. 11 Velocity broadband records of three earthquakes with similar M_w but exceptionally different rupture durations, m_B values and earthquake effects. The rupture duration D is estimated from the envelope of high-frequency P-wave radiation (gray shaded area). D corresponds approximately to the time window from the P-wave onset until the envelop amplitude drops to 40% of its maximum value (black record trace). (Copy of Fig. 2 in Bormann and Saul 2008, p. 700. With copyright granted by the Seismological Society of America)

Summary and Conclusions

The aim and historical development of magnitude scales have been sketched, systematic inconsistencies between current measurement procedures and their sometimes detrimental effects been outlined, the need for international standardization highlighted, and the recently proposed IASPEI standard procedures introduced. Reduction of magnitude errors due to incompatible measurement practices is a precondition for improving the usefulness of magnitude data for a more realistic quick assessment of differences in source physics and associated actual earthquake risk. No single magnitude value can describe the peculiarity of individual earthquakes both in terms of their tectonic size and shaking strength sufficiently reliable. A multi-magnitude documentation in earthquake catalogs and a deeper understanding of the physics behind different magnitude data is indispensable also for upgrading procedures aimed at improved medium- to long-term seismic hazards assessment.

Earthquakes and Crustal Deformation

Robert McCaffrey

Department of Geology, Portland State University, Portland, OR, USA

Definition

The term earthquake is commonly used only to describe sudden slip on a fault within the Earth that produces seismic waves in the frequency bands that we can either feel or observe with seismometers. However, other sources that produce deformation of the Earth's surface do not generate seismic waves but are instead observable with sensitive geodetic instruments that measure the crustal deformation directly. Because of the great advances over the past few decades in observing and understanding them, in this chapter we broaden the definition of earthquake to include these “quiet” sources of Earth deformation. Other chapters deal with some of these sources in more detail.

With this enhanced definition, earthquakes encompass a wide range of phenomena. The most common type we often think of is rapid slip within the Earth. The motion across a fault is typically of a shearing type but seismic disturbances can include volumetric or planar expansion in some settings, most notably near volcanoes. The classes of “earthquakes” now observed can be categorized by a rate of slip from very fast, kilometers per second, to slow, millimeters per year, covering ~ 12 orders of magnitude in slip rate. Figure 1, taken from Ide et al. (2007), shows the classes of earthquakes broken down by rate of the deformation. Because of the varying speeds of the motions, different types of instrumentation are required to cover specific bands.

Types of Earthquakes and Related Phenomena Defined

Here the types of earthquakes that produce crustal deformation are briefly defined. Many of them are described in detail in other chapters.

Tectonic earthquakes – Tectonic earthquakes are those that occur in response to plate motions or other predominantly shearing sources. They result primarily from the stick-slip behavior of faults. (Deep earthquakes occur by other mechanisms but are not discussed here as they do not visibly deform the crust.) As stress builds up across a fault surface, friction on the fault prevents the surface from sliding until the strength (some maximum shear stress) of the fault is exceeded. Then the two sides of the fault snap back (see “[Elastic Rebound Theory](#)” below), releasing some or all of the elastic strain built up. This slip occurs at several kilometers per second, releasing high-frequency seismic waves. These are by far the most common type of earthquakes and the most destructive.

Tectonic tremors – These are a new type of seismic disturbance first recognized in Japan in 2002 (Obara 2002). Originally they were called non-volcanic tremors due to some similarities to volcanic tremors. Whereas tectonic earthquakes are due to finite duration slip (on the order of seconds to minutes) on the fault, tectonic tremors appear as low amplitude, non-harmonic background disturbances lasting days to weeks. They are comprised in part of very small earthquakes but most of the signals are incoherent. Often, but not always, they accompany slow-slip events and are thought to be some aspect of the same process (Rubenstein et al. 2010).

Volcanic earthquakes – Volcanic earthquakes are similar to tectonic earthquakes in that they are due to the failure of rock along faults. However, their size is limited due to the relatively small fault surface area available near volcanoes.

Volcanic tremors – These earth disturbances are likely caused by fluid (water or magma) moving inside the earth. The signals are harmonic and can last a long time (relative to tectonic earthquakes) but are generally of low amplitude and generate little crustal deformation.

Slow earthquakes – Some earthquakes occur at slip speeds that are slower than typical tectonic earthquakes but fast enough to excite seismic waves. They occur when slip is in materials of low rigidity such as accretionary prisms of subduction zones. In such cases, they can produce tsunamis that are larger than expected for the earthquake's magnitude. Examples are earthquakes in Nicaragua (Kanamori and Kikuchi 1993) and New Zealand (Doser and Webb 2003).

Low-frequency earthquakes – Such earthquakes, called LFEs, have been observed in volcanic settings and more recently associated with tectonic tremors at subduction zones. As the name indicates they generate much lower

Earthquakes and Crustal Deformation, Fig. 1 Durations and moments of various types of crustal deformation events, modified from Ide et al. (2007). Black and gray circles and elongated bars show silent earthquakes, afterslip and slowslip events from Italy, Nankai, Kilauea, San Andreas, and Sanriku (Ide et al. 2007). Squares are slowslip events

frequencies than normal tectonic earthquakes. In both settings the low frequencies may be attributable to fluid interactions (Shelly et al. 2006).

Slow-slip events – In this class of events, called SSEs, the rupture speed is on the order of a few millimeters per day. Thus the rupture propagates at 11 orders of magnitude slower than a tectonic earthquake but only about 10 times faster than tectonic creep at plate motion rates. At these slow-slip speeds, seismic waves are not generated and slow-slip events are not detected by seismometers. To date, SSEs have been detected by geodetic instruments at subduction zones, Kilauea and on the San Andreas fault.

Post-seismic slip events – Another type of crustal motion that is often observed following large tectonic earthquakes is due to afterslip, thought to arise from continued slip on the fault at slow speeds. Afterslip can in small part be explained by aftershocks but the majority of the slip occurs without producing seismic waves. Such slip can last years and produce as much total slip as the main earthquake itself. The afterslip events often decay in accordance with Omori's Law.

Mantle relaxation – Following large earthquakes, the redistribution of the stress in the crust and mantle can cause the mantle to flow in a viscous manner, which then produces a long-period deformation of the crust above. This signal can often be confused with post-seismic slip.

from New Zealand (McCaffrey et al. 2008) and Guerro, Mexico (Larson et al. 2007). These follow a scaling relation of $\sim M_0/t$. Typical scaling relation for regular shallow interplate earthquakes is shown by the blue line. (See Ide et al. (2007) for additional information)

Induced earthquakes – Earthquakes are induced by the activities of humans that modify the stress at shallow depths in the Earth. Examples of such activities are mining, drilling, and water impoundment behind dams. Induced earthquakes tend to be of significant hazard because they are very shallow and close to infrastructures (see ▶ “Artificial Water Reservoir-Triggered Earthquakes, with Special Emphasis on Koyana, India”).

Fault morphology – Most deformation of the crust is accommodated by faulting. Crustal faults are the lasting expressions of past earthquakes and provide a means via geologic investigations to characterize the earthquakes. Compilations of estimates of slip rates and fault lengths are used to calculate long-term (Holocene, for example) deformation rates in continental regions.

Elastic Rebound Theory

Large earthquakes, as noted above, are caused by slip on crustal faults and exhibit stages of strain build-up and release known as the earthquake cycle. A simple form of this cycle is elastic rebound. The concept of elastic rebound as relating to the earthquake cycle was first introduced by Harry Reid (Reid 1910) following earthquake observations in Sumatra and California. (See the interesting, in-depth description of the history of elastic rebound by Segall 2010.) In this description,

Earthquakes and Crustal Deformation, Fig. 2

Illustration of the elastic rebound effect. The fence originally built in a *straight line* across the fault (a) is deformed by the strain around the fault in the period leading up to an earthquake (b). In (c) the earthquake has offset the fence but also straightened it again by the release of the strain. (d) Measured and modeled co-seismic offsets near Parkfield CA resulting from the 2004 M6 earthquake. (Redrawn with permission from Barbot et al. 2009)

the crustal blocks adjacent to a fault are stuck together by friction on the fault surface and their relative movement causes strain in the blocks (Fig. 2a, b). The material comprising the upper crust is thought to be linearly elastic, so the strain increases over time in a steady fashion as long as the blocks move at the same speed. At some point, the stress on the fault reaches its strength, and the fault slips suddenly in an earthquake (Fig. 2c). The strain accumulated over decades to centuries is relieved in a matter of seconds. The slip on the fault causes the stored strain energy in the crust to be converted to kinetic energy which in turn is emitted as seismic waves and heat and the stress on the fault drops to a lower level. The use of the word “rebound” in this case refers to the idea that any feature on the surface, such as a fence crossing the fault, will return to its original shape (i.e., free of strain) after the earthquake (Figs. 2 and 3). The earthquake in a broader sense produces permanent strain on a regional scale by displacing the crustal blocks along the fault (and offsetting the fence). Many observations of earthquake deformations have validated the elastic rebound model – the example of the 2004 Parkfield, California, earthquake rebound is shown in Fig. 2d (Barbot et al. 2009).

We have discovered in the past few years that elastic rebound pertains not only to earthquakes of the type Reid

observed, but also to earthquake afterslip (Heki et al. 1997) and so-called “slowslip events” (Dragert et al. 2001). In these phenomena, illustrated by GPS time series shown in Fig. 4, slip on faults can occur at much slower rates than it does during earthquakes. In these time series showing the position of a point on the ground, the steady motion of the linear earthquake cycle is interrupted not only by earthquakes (abrupt offsets in Fig. 4a) but also by afterslip that decays with time. In slowslip events, the linear site motion is interrupted for weeks to months (Fig. 4b) in Cascadia and New Zealand, for example. The spatial pattern of the slip and our knowledge of the rebound cycle guide our interpretation of these anomalous signals as slip on the fault surface.

The simple picture of elastic rebound theory is a good conceptual view of the earthquake cycle but in detail we see that it is much more complex. As more and better observations are made we see that the earthquake cycle includes time-dependent deformations on many time scales. These are discussed next.

Pre-seismic Crustal Deformation

The deformation of the Earth’s surface leading up to earthquakes has been of great interest to scientists for a long time

Earthquakes and Crustal Deformation, Fig. 3

Picture taken in Marin County shows a fence that was offset about 10 ft. along the trace of the San Andreas fault by the 1906 earthquake. (Photo attributed to G.K. Gilbert; <http://america.hurrah.com/USGS/26.htm>)

due to the quest to identify precursors for prediction purposes. Such deformation can be grouped into long-term and short-term signals. For the long-term, the Earth deforms in the vicinity of faults largely in roughly the elastic rebound manner described above. Mapping out the temporal changes in crustal strain near faults is being used extensively to identify which parts of the fault are being loaded, or being subject to stress increases. In a simple sense, the parts of the fault being loaded may help delineate the future rupture region but the details are far from clear. For example, the current rate of loading of the Cascadia subduction thrust is inferred from the results of 15 years of GPS observations by McCaffrey et al. (2007) (Fig. 5) and has the important implications for how close to populated regions the rupture may come during a large subduction earthquake. Such studies have been conducted for most subduction zones and continental transform faults globally and the relationship of such loading to seismic slip is just starting to be understood.

A now common approach to understanding the crustal deformation between earthquakes (also called the *interseismic* phase) is through the use of block models (Matsu'ura et al. 1986; McCaffrey 2002; and many others). This method uses the idea that the crust or lithosphere is comprised of discrete entities (blocks) that are bounded on their lateral sides by other blocks and at their base by a stress-free region (asthenosphere). The lateral boundaries between the blocks are described by their frictional properties (i.e., a stuck fault). The blocks themselves rotate on the Earth's surface and so the motion can be described by an angular velocity (Euler pole) with its origin at the center of the Earth. Frictional interactions with adjacent blocks cause elastic strains to build in the blocks. Hence, new GPS observations

contain information about both the angular velocities of the blocks (and slip rates of their bounding faults) and the frictional properties of the bounding faults. A recent example of this is the January 2010 M 7.0 Haiti earthquake – block modeling by Manaker et al. (2008) had shown that a M ~7.2 was possible for the Enriquillo Fault in Haiti (of course such modeling does not tell when such an event will occur).

Another approach to understanding crustal deformation is to assume that at some depth below the surface, the deformation field is continuous and that the surface faulting is only a vague reflection of that motion (England and McKenzie 1982), in a similar fashion that floating ice blocks may show the general, but not specific, flow pattern of the water beneath. In this case, the surface faulting can be related to the continuous deformation field only in a statistical manner and the deformation field cannot be used to predict slip on unknown faults. On the other hand, the continuous deformation approach can be more readily related to the forces driving deformation through an assumption that the deformation is controlled by a viscous, rather than elastic, Earth. (The assumption of a viscous medium is required to relate our observations of deformation rates to forces.) For example, Jones et al. (1996) relate crustal deformation in the western USA to gravitational forces arising from spatial variations in crustal thickness acting on a viscous medium.

Short-term crustal deformation around faults leading up to earthquakes is much more elusive. To date there have been few or no convincing cases of isolated changes in deformation in the days to months prior to a large earthquake. Mogi (1985) shows evidence for accelerated uplift at tide gages in the 5 years preceding the 1983 Sea of Japan earthquake (see also Scholz 2002). This evidence must be considered less

Earthquakes and Crustal Deformation, Fig. 4

(a) The east position of continuous GPS site SAMP in northern Sumatra leading up to and following the December 2004 and March 2005 great earthquakes at the Sumatra subduction zone. The earthquakes each caused large sudden offsets of about 100 mm. The afterslip, which decays in a logarithmic fashion, produced over 100 mm of additional motion in the 3 years following the earthquakes. (b) GPS time series from Cascadia and New Zealand showing the geodetic signature of “slowslip” events. These events produce offsets of the time series but, unlike earthquakes, the offsets occur over weeks to months, rather than minutes. The *solid lines* show the linear trends (steady site velocities) between the slip events

certain than it was a few years ago before we knew of slowslip events. Although no SSEs have been observed in the past 10 years on modern GPS equipment in the vicinity of the 1983 earthquake, we cannot rule out that the pre-earthquake uplift was due to slowslip on the fault that subsequently ruptured (or some other fault) rather than a useful precursory change prior to the quake. (Because many SSEs have occurred without triggering tectonic earthquakes, we know that slowslip events are NOT short-term precursors to earthquakes.)

Co-seismic Crustal Deformation

The term co-seismic refers to the time right around the earthquake when the fault rupture is still propagating and seismic waves are being generated. Generally this amounts to a few

seconds for a magnitude 6–7 earthquake and a minute or more for $M > 8$. The 2005 M9.3 Sumatra earthquake is thought to have ruptured for about 5 min – this is the time it takes to rupture such a long fault (~1300 km) at typical rupture speeds (~3–4 km/s). Earthquakes generate both dynamic displacements, those that propagate but return to their original positions after the waves pass, and static displacements that are permanent. Seismometers can record the dynamic motions within their pass band but cannot measure the static displacement which requires geodetic instrumentation. Both the dynamic and static displacements induce stress changes in the crust and mantle that can lead to other forms of crustal deformation, such as triggered earthquakes, afterslip, slowslip and mantle relaxation. While GPS observations can measure the passing waves for very large earthquakes (as can seismographs), we are more concerned here with the static displacements.

Earthquakes and Crustal Deformation, Fig. 5 Frictional loading of the Cascadia subduction zone inferred from crustal deformation of the coastal regions measured with 15 years of GPS observations (McCaffrey et al. 2007). The locking rate is the rate at which the subducting plate pushes the base of the overriding plate landward. This rate, integrated over time, provides an estimate, according to elastic rebound theory, of how much slip might occur in a large strain-relieving earthquake. Contours are of the depth to the plate boundary interface, in kilometers

The static displacements from a large earthquake provide much information on the faulting process and can be measured by comparing the position of ground points before and after the earthquake (Fig. 2d). However, because the points are moving constantly due to tectonic plate motions and fault-induced elastic and anelastic strain, as discussed above, it is not always easy to know where the points were just prior to the earthquake. Consequently, in many active regions of the world, GPS data are collected continuously (called continuous GPS, or cGPS) which provide a direct measure of the prequake position. However, such observatories are expensive and generally not sufficiently dense to characterize the earthquake details when one happens. The geodetic characterizations of most earthquakes are now based on a combination of

cGPS and survey-mode GPS, where measurements are made intermittently.

Simple physical representations of the Earth have been quite successful in characterizing the slip during large earthquakes based on the observed static displacements. (Seismic waves are also used to estimate the slip distributions of earthquakes – see ▶ “Earthquake Source Theory”). The most commonly used structure and source representation is the elastic, half-space dislocation (see Segall 2010). The popularity of this method owes to the simplicity of the algorithm published by Okada (1992, 1995) for use in three dimensions and its success in reproducing the observations. More times than not, the geodetic and seismologic representations of an earthquake source agree within the levels of accuracy. In fact, when they do not agree, the blame is often placed on the complexity of the source rather than on the techniques.

Such studies of the distributions of slip on the fault during earthquakes have shown us just how complex the slip can be. It remains enigmatic why the earthquake slip distributions (fault unloading) are so much more heterogeneous than the loading distribution (as estimated from interseismic studies as discussed above). This is one of the challenges facing us if we want to use contemporary fault loading measurements to understand the real earthquake hazards.

Post-seismic Crustal Deformation

Unlike pre-seismic deformation, many striking examples of post-seismic deformation have been documented for large- and moderate-magnitude earthquakes. The mechanisms of this deformation are most likely either continued slowslip on the fault or adjustment of the viscous mantle or lower crust to the changes in stress brought about by the earthquake.

It has been known for a long time that large, shallow earthquakes produce aftershocks that decay with time (t) in a $1/t$ fashion. This aftershock decay was explained by the changes in friction on the fault as the slip rate decayed, known as Omori’s Law. Continued slip on faults after large earthquakes sometimes shows a similar decay and this decay follows Omori’s Law as well (though the total slip is many times greater than what can be explained by aftershocks alone). The first clear example of significant afterslip was for the 1994 Japan Trench earthquake observed by Heki et al. (1997) where the relatively aseismic afterslip exceeded the co-seismic slip magnitude in the year following the earthquake. The 2004 Parkfield earthquake was followed by aseismic afterslip that was about three times the co-seismic slip (Johanson et al. 2006).

We now describe the magnitude of an earthquake or any other slip event with the moment-magnitude scale. For a slip event on a fault, the moment M_o is defined as the average slip magnitude times the area of that slip times the rigidity modulus

of the rocks around the fault, and the magnitude is $M_w = 2/3 \log(M_o) - 9.5$ (Hanks and Kanamori 1979). Hence moment can be based on either seismic or geodetic measures of the slip and area and these can be compared. By making such comparisons we now understand that aseismic afterslip (or slowslip) contributes as much or more to the total slip budget on some faults as do earthquakes. This discovery has positive implications for earthquake hazards in the sense that seismic events of a given size may be less frequent than previously estimated.

Observational Advances and New Discoveries

Our knowledge of the existence of the various types of earthquakes and their structures and our understanding of them rely on our ability to detect them and explain the observations. In the past 20 years, great advances in instrumentation have led directly to the detection of some new types of deformation sources. They, along with new analytical algorithms, have greatly advanced our understanding of earthquakes and crustal deformation. Here, we describe some of these new methods and the important discoveries that they have allowed.

Possibly the greatest advance in the past couple of decades has been in the use of remote sensing in earthquake and crustal deformation studies. These new methods include the Global Positioning System (GPS), Interferometric Synthetic Aperture Radar (InSAR), and Light Detection and Ranging (LIDAR). The first two of these allow us to measure displacements of the Earth's surface using information obtained from satellites orbiting the Earth. With repeated measurements we can watch the temporal variations in surface deformation with great accuracy. LIDAR is allowing unprecedented resolution of the topography of the Earth's surface beneath the biological layer and has delineated geologic structures (faults) in regions that are too remote or forest-covered to find otherwise.

GPS, in particular when used in the differential mode, has resulted in the detection of the large, slow movements along faults – slowslip, post-seismic, afterslip, and mantle relaxation described above. Today, thousands of GPS instruments operate continuously at sites around the globe providing daily estimates of the site's three-dimensional position, which can be combined to form the equivalent of a displacement seismogram. The positional accuracy achieved for any given day is on the order of a few millimeters. The signal can also be sampled at a smaller time interval, such as seconds, to record the passing seismic waves in addition to the total static displacement produced by the earthquake. Such a resampling is possible only for very large earthquakes where the ground motions exceed a few millimeters. However, the greatest contribution of GPS has been in the discovery of crustal deformation sources that do not produce seismic waves.

The knowledge that fault movement could occur at rates somewhere between fast slip (km/s) and creep (mm/year) has

been with us for years – such motions were observed on strain meters near the San Andreas fault in California (e.g., Linde et al. 1996). However, these slip events were very small compared to sizes of earthquakes on the fault. As described above, the observation by Heki et al. (1997) that post-seismic slip exceeded the slip during the earthquake itself was remarkable as it changed our ideas about how often earthquakes should occur on a given fault. In other words, we could no longer expect that the total slip on a fault in a given time period would be accompanied by earthquakes, an idea that held its roots in elastic rebound theory. Instead, some large portion of fault could slip without earthquake shaking.

As remarkable as that discovery was, in 1999 Dragert et al. (2001) recorded in the Western Canada Deformation Array (continuous GPS network) a very slow deformation of the ground that looked just like a $M \sim 6.7$ earthquake, except that it occurred over 2 weeks time instead of just a few seconds. The maximum surface displacement was only 5 mm and at the time no seismic waves were detected. The slow surface deformation was interpreted by them to be due to slip on the Cascadia subduction fault directly beneath the GPS network. The slip on the fault was very slow, amounting to only 2 cm over the 2 weeks – this was 12 orders of magnitude slower than slip during a normal earthquake (~ 3 km/s).

Around the same time, Obara (2002) discovered the presence of low-level incoherent but intermittent seismic signals, called *tectonic tremor* above, coming from the subduction fault beneath Japan. Importantly, these signals appeared to originate on the fault just below the deepest slip extent from recent large earthquakes. Initial suggestions were that the tremor coincided in space and time with slowslip (Rogers and Dragert 2003) but additional studies of both phenomena have not borne that out. Further detailed studies of tectonic tremor requiring new seismological techniques revealed that it is likely in part due to numerous small thrust earthquakes (LFE), on the subduction thrust boundary (Shelly et al. 2006). However, when they occur together, the total slip that can be accounted for with these small quakes is far less than what is seen in the slowslip events. Hence, it appears that the majority of the slowslip is indeed seismically silent.

While GPS provides a fine temporal sampling of the deformation, it is generally sparse in the spatial dimension because continuous GPS installations are expensive. The use of differential satellite interferometry (InSAR) has helped fill in the spatial gaps in pictures of the deformation of the Earth's surface by earthquakes and volcanoes. The InSAR method uses the interference patterns between two or more radar images of the ground that have been obtained from satellites. Comparing the images allows estimation of the displacement of the ground in the direction of the satellite (the LOS or line-of-sight component). The method relies on the ground surface changing at long wavelengths only, so that the images have strong

Earthquakes and Crustal Deformation,

Fig. 6 Interferogram showing the ground deformation observed during the December 2003 M6.6 Bam, Iran, earthquake (http://neic.usgs.gov/neis/eq_depot/2003/eq_031226/). On *left*, the “wrapped” image shows line-of-sight (LOS) displacements by the phase of the difference in distance to the satellite; on the *right* the image has been “unwrapped,” that is, converted to distance changes. In both cases the four-lobe displacement field of the strike-slip earthquake is evident. (Image with permission from Funning et al. 2005)

correlation (coherence) and can be matched. InSAR provides a scalar observation of the deformation but at high spatial density (Fig. 6) whereas GPS provides a vector of the deformation at high temporal sampling. Many studies use GPS and InSAR together to characterize the deformation, taking advantage of the strengths of both types of observations.

The LIDAR method is extremely useful in detecting faults that intersect the ground surface. Because it uses shorter wavelengths than radar, it allows us to see finer features. Very often, faults produce only subtle lineations on the ground surface, which can now be detected at the sub-meter level. While LIDAR does not give details of the fault, like the slip rate, it can pinpoint targets for additional field study. An example of the utility of the LIDAR method is the delineation of the Seattle Fault in northwestern Washington state (Haugerud et al. 2003). This fault, which crosses the highly populated Puget Sound region, produced a large earthquake about 1,100 years ago. The fault scarp is large and obvious in some places but subtle and covered in forests in others.

The advance of the new geodetic techniques has had such a positive impact on geophysics that major organizational steps have been taken to utilize them. The consortium of universities called UNAVCO (University Navstar Consortium; unavco.org) was developed to support the global research community in the use of geodetic tools. In several countries, permanent dense geodetic networks and similar consortia have been established to monitor earthquakes and their associated phenomena.

Perspectives

Our ideas about earthquakes *sensu strictu* have undergone drastic changes in the past few years. Elastic rebound theory, while still a sensible conceptual model, does not cover the

large range of observed phenomena that make up the earthquake cycle. A clear challenge that still faces us is to tie together the various deformation processes we observe throughout the cycle into a comprehensive earthquake theory. Some of the more important goals are to understand the observations we make in terms of future earthquake risk. For example, although we can measure current loading of faults quite well by its elastic strain near the fault, we do not know what it means for the slip distribution in future events. Geodetic methods of measuring crustal deformation have a short history relative to the times between large earthquakes, so geologic methods including paleoseismology (see ► “Paleoseismology”) and LIDAR that extend the observation history are crucial. Continued study and understanding of the aseismic slip events and tectonic tremor on faults may pay big dividends toward delineating the parts of the faults that are prone to seismic slip during large destructive earthquakes. The acquisition of deformation data at high resolution in both time and space will assist greatly in understanding processes operating at depth within the Earth.

²National Geophysical Research Institute (CSIR), Hyderabad, India

Definition

Earthquake: Sudden release of elastic strain energy along a fault.

Himalayan arc: About 2500 km long mountain chain running from Afghanistan, Pakistan, India, Nepal, China, and Myanmar, formed due to collision/subduction of Indian and Eurasian plate.

Main Himalayan thrust: The contact surface between the underthrusting Indian plate, and the overlying Himalayan wedge rocks.

Introduction

With the advent of modern concept of plate tectonics “*Himalaya-Tibetan orogenic system*,” a classical subduction-collision plate boundary zone has attracted the attention of geoscientists globally, who have considered it as a “*geodynamic black box*.” Himalayan geodynamics, its genesis, earthquake occurrence process, and associated lithospheric deformation have largely been considered within the framework of the collision of the Indian and Eurasian plates at some period during the Eocene (~50 Ma), resulting in the subduction of the Indian plate below Tibet. This has resulted in intense crustal shortening and deformation, taken up by crustal stacking along a system of intracontinental thrusts

and internal deformation of adjacent Tibet and Indian plate (Murphy et al. 2009; Styron et al. 2011).

In the present entry, we have tried to focus on Himalayan earthquakes, in view of advances in knowledge about the past ~1000 years of earthquakes' occurrence processes, constrained by geodetic, historic, and seismological data, along the Himalayan arc in order to objectively assess seismic hazard of the region and adjoining Indo-Gangetic plains (~250 million hectares fertile plains), which is one of the most densely populated regions of the Southeast Asia accommodating ~40% of the India's population. In addition to that, significant high relief of the Himalayan Mountains blocks the northward monsoonal winds from the Indian Ocean during June–September, resulting in intense orography-controlled precipitation, and associated seasonal water mass accumulation and mass redistribution by the Himalayan river system, which dominate the regional surface loading process along the arc. Further, this seasonal non-tectonic deformation also influences the tectonic deformation along the Himalayan convergent plate boundary, making Himalayan earthquake

occurrence and associated deformation process much more complicated. Rather than repeating what has already been documented in a few excellent reviews (e.g., Bilham et al. 2017; Bilham 2019), we have attempted to add more information from the perspective of crustal deformation.

Geodynamic Models of Himalaya-Tibetan Orogenic System

The Himalaya-Tibetan orogeny has always remained a key domain for scientific community in terms of geodynamic evolution and tectonic complexity. Deformation pattern along this subduction-collision plate boundary has been explored widely (Copley and McKenzie 2007; Murphy et al. 2009; Styron et al. 2011); however, there are several issues which are still unexplored. Several geodynamic models have been proposed in order to explain the geometry and active tectonics along the Himalaya-Tibetan orogen (Styron et al. 2011). These models are (Fig. 1): (a) *Lateral extrusion*

Earthquakes in the Himalaya, Fig. 1 Geodynamic models for Himalayan and south Tibetan deformation. (After Styron et al. 2011). The gray arrows represent motion of the Tibetan crust for different models. The

black arrow in oblique convergence model represents the overall India-Southern Tibet convergence. KF: Karakorum Fault; EHS: Eastern Himalayan Syntaxis; WHS: Western Himalayan Syntaxis

model that deals with the ductile flow and associated distributed deformation of the Tibetan crust; (b) *Oroclinal bending* which implies the curvature of the Himalayan arc and deformation associated with it; (c) *Lateral spreading* that is concerned with the outward radial expansion of the Tibetan Plateau; and finally (d) *Oblique convergence model* that deals with the variable obliquity in the convergence and deformation along the Himalayan arc (Styron et al. 2011; Li and Yin 2008; Murphy et al. 2009). Out of these four, there are two popular models that have been widely accepted in recent past, namely, lateral extrusion model and oblique convergence model.

Following the oblique convergence model in NW-Himalaya, Kundu et al. (2015) proposed that the India-southern Tibet oblique motion is being partitioning in the backarc as dextral motion along the Karakorum fault system, thereby developing the NW-Himalayan sliver. Similarly, upon applying the oblique convergence model in NE-Himalaya, one should expect a sliver with left lateral motion in the backarc. However, geomorphic offsets, geodetic estimates and the available earthquake data do not support the presence of any active left-lateral fault system in the region (Woerd et al. 2009). Thus, it appears that the oblique convergence model and lateral extrusion model are mutually contradictory in view of the tectonics and distributed deformation (or slip partitioning) in the NE-Himalaya. In order to resolve this issue, Panda et al. (2018a) proposed that instead of partitioning the backarc, the NE-Himalaya has developed an active sliver along the Assam-Brahmaputra

valley in the outer deformation front to accommodate the oblique motion through distributed deformation. This suggests the complex deformation behavior along the Himalayan arc and indicates that there is no unified model (or mechanism) that can explain the whole deformation process along the arc.

Crustal Deformation and Strain Buildup Along Himalayan Arc

In the past few decades with the advancement of geodetic techniques and relatively good spatial coverage of GPS measurements spanning the Himalayan arc, more insight has been gained into the deformation behavior and associated seismic potential along this subduction-collision plate boundary. GPS observations of surface displacement indicate that the Himalaya accommodates about ~ 20 mm/yr. of convergence rate between India and Eurasia (Stevens and Avouac 2015) (Fig. 2). However, the overall convergence rate decreases in the North-Western Himalaya to 13 mm/yr. (Kundu et al. 2014; Schiffman et al. 2013) and North-Eastern Himalaya to 16 mm/yr. (Panda et al. 2018a; Vernant et al. 2014). All along the Himalayan arc, the Main Himalayan Thrust (MHT) appears to be fairly uniformly locked from the surface to beneath the front of the high ranges of the Higher Himalaya over a width of 100 ± 20 km, which suggests high seismic hazard in the frontal ranges (Stevens and Avouac 2015). The Himalayan range has indeed produced a number of great earthquakes recently (e.g.,

Earthquakes in the Himalaya, Fig. 2 Interseismic coupling model (marked by red) of the Himalayan arc derived from GPS measurements. A coupling value of 1 means the portion is fully locked, while 0 means the region is fully creeping. Black and blue arrows represent observed

and modelled GPS velocities with respect to fixed India reference frame. Red arrows are the averaged velocities of the particular segment along the arc, which are separated by dashed lines. (After Stevens and Avouac 2015)

M7.8 Gorkha 2015, M6.9 Sikkim 2011, and M7.6 Kashmir 2005) and even larger historical earthquakes (e.g., M8.5 Assam 1950; Chen and Molnar 1990 and M8.2 1934 Nepal-Bihar earthquakes; Sapkota et al. 2013). However, still more than two-thirds of the Himalayan arc has not experienced a great earthquake in the past 200 years (Bilham and Wallace 2005) and most of the unruptured Himalayan segments may have the potential to generate great earthquakes (Bilham et al. 2001).

In case of central Himalaya (i.e., Nepal Himalaya), all the ~ 20 mm/yr. of convergence is accommodated through thrust motion and such high strain rate is consistent with higher seismic hazards as compared to the adjacent NE and NW-Himalaya (Stevens and Avouac 2015). In case of NW-Himalaya (i.e., Kashmir Himalaya), GPS observations indicate the overall convergence between India-southern Tibet to be ~ 13 mm/yr. and the remaining oblique motion is accommodated through dextral strike slip motion along the Karakorum fault system in the backarc forming the NW-Himalayan sliver (Kundu et al. 2014) (Fig. 3). It appears that the convergence rate in the Kashmir frontal Himalaya is about 25% less than that in the Nepal Himalayan region and so is the seismic potential, assuming that the entire convergence occurs through stick-and-slip motion without any significant aseismic motion. Similarly, in the NE-Himalaya (i.e., Bhutan and Arunachal region), the overall convergence rate accommodated in the Himalayan arc is about 20–25% less than that in the neighboring central Himalaya (Panda et al. 2018a; Vernant et al. 2014).

Panda et al. (2018a) explained such low convergence rate in NE-Himalaya due to the presence of Assam-Brahmaputra valley sliver in the outer deformation front (Fig. 3). Presence of

such sliver in the outer deformation front may be attributed to the low strength of the crustal material and therefore it tentatively implies a lower seismic hazard. However, tectonics and earthquake occurrence processes of the two Himalayan syntaxes are complex and relatively less understood, due to poor accessibility and limited investigations on crustal deformation patterns. GPS measurements of crustal deformation across the eastern Himalayan syntaxis (EHS) indicate ~ 20 mm/yr. of convergence across it due to India-Eurasia oblique convergence (Devachandra et al. 2014). Convergence across the EHS is accommodated through stick-and-slip process, where the 65 km wide main thrust zone of the plate boundary interface is locked, which significantly increases the seismic vulnerability of this region.

Mid-Crustal Seismicity and Associated Seismic Swarm Along Main Himalayan Thrust

Interseismic strain accumulation process across the Himalaya (Lave and Avouac 2000; Ader et al. 2012; Stevens and Avouac 2015) is also associated with the micro-seismicity (also called as mid-crustal seismicity), which occurs at a depth of 10–20 km on the Main Himalayan Thrust, MHT (Fig. 4). These smaller magnitude earthquakes (M 2–4) are considered to occur on and above the base of seismogenic MHT (Bollinger et al. 2007). However, the very accurately located aftershocks of the 2015 Gorkha earthquake provided evidence that they are mainly associated with the duplex structure (Mendoza et al. 2019). Earthquake focal mechanism solutions, which mainly describe the nature of faulting and orientation of the fault planes,

Earthquakes in the Himalaya, Fig. 3 Comparison between backarc and outer deformation-front strain partition in two different convergent plate margins. (a) In South America, the Nazca plate is subducting beneath the South American plate. Due to the arcuate geometry of the arc, the overall motion (blue arrow) is partitioned into arc parallel (gray arrow) and arc perpendicular (red arrow) component. The arc perpendicular component contributes to convergence, while the arc parallel component partitioned in the backarc on either side of the arc to produce two largest continental slivers (i.e., Ecuador and Peru sliver) on the

backarc. (b) Indian plate is subducting beneath the Eurasia plate and due to the shape of the Himalayan arc, the motion should partition in the backarc on either side of the arc. In NW-Himalaya, the oblique motion is partitioned on the backarc as dextral motion along the Karakorum fault system, thereby creating the NW-Himalayan sliver. However, in NE-Himalaya, due to presence of strong eastward flow of the Tibetan crust in the backarc, the motion is partitioned on the outer deformation front along the Assam-Brahmaputra valley. KF: Karakorum Fault; JF: Jiali Fault; EHS: Eastern Himalayan Syntaxis. (After Panda et al. 2018a)

Earthquakes in the Himalaya, Fig. 4 Conceptual model describing the effect of the hydrological mass oscillation along the North-South profile of Nepal-Himalaya region. (After Panda et al. 2018b). Yellow symbols represent mid-crustal seismicity at the base of the seismogenic zone (i.e., mid-crustal ramp). GSZ: Galchi shear zone; GT: Gorkha blind

Thrust; MHT: Main Himalayan Thrust; STD: South Tibetan Detachment; MCT: Main Central Thrust; MT: Munsiri/Mahabharat Thrust; RT: Ramgarh Thrust; MBT: Main Boundary Thrust; MDT: Main Dum Thrust; MFT: Main Frontal Thrust

indicate predominantly thrust motion on the shallow dipping MHT (Rajaure et al. 2013). This narrow and spatially distinguishable seismicity belt roughly coincides with the topographic front of the Himalaya in Nepal (i.e., 3.5 km contour), also considered as the down-dip edge of the locked portion of the MHT (Avouac 2003; Bollinger et al. 2004). A few magnetotelluric studies confirm the presence of fluids at the base of seismogenic MHT, where the micro-seismicity occurs (e.g., Lemonnier et al. 1999; Rawat et al. 2014; Hoste-Colomer et al. 2018). A few earthquake swarms have been reported from Nepal Himalaya (Hoste-Colomer et al. 2017) and Garhwal-Kumaun Himalaya (Paul and Sharma 2011; Singh et al. 2018), which also imply the presence of fluids in these regions.

As discussed above, the micro-seismicity (or mid-crustal seismicity) belt along the Himalaya is located on the base of the seismogenic MHT and on the duplex structure above it, which is considered to be the transition between the velocity-weakening (favoring earthquakes) to velocity-strengthening (suppressing earthquakes) domain or conditionally stable frictional regimes. This segment is very much sensitive to external stress perturbations by climatic loading. So, there is a possibility that these micro-earthquakes may be modulated by external periodic load perturbations. Bettinelli et al. (2008) proposed seasonal modulation of micro-seismicity in the Himalaya, which are controlled by surface water load variations. The seismicity rate is twice as high in the winter as in the summer, and correlates with stress rate variations due to continental water storage oscillations (Bollinger et al. 2007; Bettinelli et al. 2008). Although the stress change due to such external surface load variations are very small, but presence of high pore pressure at seismogenic depth may cause seismicity

modulation that is controlled by seasonal variations. Similarly, Kundu et al. (2017) found strong annual periodicity in the mid-crustal seismicity, in response to the annual stress variation of hydrological loads. They reported strong annual periodicity in the eastern Nepal as compared to that in the western Nepal, with prominent annual periodicity in the small magnitude earthquakes (Kundu et al. 2017). Rainfall and seismicity cross correlation is also significantly higher in the eastern Nepal region as compared to that in the western Nepal with a prominent phase lag of 5–6 months with respect to the occurrence of monsoonal rainfall (Kundu et al. 2017) (Fig. 5). These studies confirm that during the post-monsoon period (i.e., during winter), significant component of horizontal compression is added to the interseismic contraction at the MHT, which is the main driving mechanism for the seasonal modulation of micro-seismicity in Nepal Himalaya (Kundu et al. 2017).

Factors Influencing Himalayan Earthquakes

Role of Subducted Ridge

It has been reported extensively in several literatures that subduction of diverse type of bathymetric features (e.g., seamounts, aseismic ridges, fractures, banks and rises, etc.) influences the location and frequency of great earthquakes in subduction zones and also significantly alters the arc morphology (Rosenbaum and Mo 2011; Robinson et al. 2006; Bilek 2007; Das and Watts 2009; Watts et al. 2010). In this context, it appears that spatial extents of historic and recent great Himalayan earthquakes are also influenced by at least three major subsurface ridges (e.g.,

Earthquakes in the Himalaya, Fig. 5 Temporal correlation between mid-crustal seismicity, snow depths in Higher Himalaya and rainfall in the surrounding region. Different gray bars represent different magnitudes of mid-crustal seismicity. Note that the seismicity peaks correlate

with the peak rainfall with a phase lag of ~ 6 months. Light shade region represents the period of bad network geometry, which is excluded from the analysis. (After Kundu et al. 2017)

from east to west Monghyr Saharsa ridge, Faizabad ridge, Delhi Hardwar ridge) that have been mapped on the underthrusting Indian plate beneath the Indo-Gangetic plains (Valdiya 1976; Gahalaut and Kundu 2012) (Fig. 6). It has been proposed that the subduction of the two most prominent ridges namely the Chagos-Laccadive-Deccan ridge and the 90°E Ridge contributed to the development of the arcuate shape of the Himalayan arc. The interaction and subduction of the other subsurface ridges probably influenced the Himalayan arc morphology by causing a localized cusp in the frontal topography and further these ridges probably acted as barriers to the ruptures of the major and great Himalayan earthquakes (Gahalaut and Kundu 2012). These barriers are considered to be the regions of low friction which do not allow the rupture to propagate further, thereby arresting the rupture propagation.

Stress Triggering Process

Generally, earthquakes have potential to modify the stress regime of the critically stressed fault system, extending into brittle crust predominantly over a variety of spatiotemporal

scales by three partially overlapping categories: (a) static stress (stress change decays rapidly with distance (d) from the epicenter as d^{-3}); (b) quasi-static stress (decay as d^{-2}); and (c) dynamic stress (decay as $d^{-1.5}$ for surface waves) (Prejean and Hill 2014).

Such earthquake triggering phenomenon is also reported from the Himalayan arc in a few studies (Gahalaut et al. 2011; Mendoza et al. 2016). It has been argued that the seismicity of the Bhutan Himalaya region is generally low as compared to its adjacent Himalayan segments. It has been suggested that the lower seismicity in the Bhutan Himalaya may be due to static stress change by the great 1897 Shillong Plateau earthquake (Gahalaut et al. 2011). The low seismicity region of the Bhutan Himalaya clearly coincides with the static stress shadow of the 1897 Shillong Plateau earthquake. (Fig. 7a, b) In addition to that, seismically active Kopili Fault segment in Assam-Brahmaputra valley and some of the dextrally slipping transverse faults system of Himalayan region coincides with the positive static stress change, caused by the 1897 earthquake rupture (Fig. 7c, d). Therefore, it appears that

Earthquakes in the Himalaya, Fig. 6 Seismicity of the Himalayan arc, general geology, rifts in the Tibetan plateau and subsurface ridges in the Indo-Gangetic plains. (After Gahalaut and Kundu 2012). (a) Blue dots represent seismicity along the Himalaya and surrounding region. Different ridges are marked by light shaded color. Gray arrow represents

India-Eurasia convergence. (b) Variation of seismicity ($M > 4.5$) of the Himalayan Seismic Belt (HSB) in an overlapping and sliding 50 km window. DHR: Delhi Hardwar ridge; FR: Faizabad ridge; MSR: Munger-Saharsa ridge; MFT: main frontal thrust; MBT: main boundary thrust; MCT: main central thrust

1897 Shillong Plateau earthquake has altered stress regime of the Himalaya and adjacent segments up to some extent.

Besides the static stress triggering effect, Mendoza et al. (2016) reported the observation of remote dynamic triggering of local micro-earthquakes in the central Himalaya, caused by the teleseismic waves from the M8.5, 2007 Sumatra earthquake which occurred ~4500 km away from this region. It has been argued that the Himalayan fault systems in the central Himalaya region are extremely sensitive to small stress changes of about ~9 kPa of peak dynamic stresses imparted by the teleseismic waves (Mendoza et al. 2016). We are hopeful to detect more examples of dynamic triggering with better seismic station coverage in the Himalayan arc.

Non-tectonic Deformation

Besides tectonic process, there are several non-tectonic processes that can also significantly deform Earth's crust and may

cause seismicity modulation. These non-tectonic processes may include continental water storage (Blewitt et al. 2001; Bettinelli et al. 2008; Steckler et al. 2010; Fu et al. 2013; Chanard et al. 2014), tidal loading (Agnew 1996, 1997), ice and snow load (Matsuo and Heki 2010; Jiang et al. 2010), heavy precipitation (Hainzl et al. 2006), atmospheric pressure and disturbances (Kaniuth and Vetter 2006; Liu et al. 2009), sediment unloading by river incision (Calais et al. 2010), reservoir impoundment (Gupta 2002), etc.

Considering the continental water storage (or hydrological load) variation, the Amazon basin experiences the largest seasonal mass variation because of heavy rainfall, followed by the Southeast Asia where the hydrological load variations are controlled by strong monsoonal rainfall. The hydrological load variations are measured by Gravity Recovery and Climate Experiment (GRACE) and are expressed in terms of equivalent water height (EWH). Strong seasonal horizontal

Earthquakes in the Himalaya, Fig. 7 Coulomb failure stress change (Δ CFS, in bar) on Himalayan detachment (~10 km depth) caused by 1897 Shillong Plateau (SP) earthquake. (After Gahalaut et al. 2011). (a) Δ CFS on optimally oriented planes using earthquake rupture model of Gahalaut and Chander (1992). (b) Δ CFS on optimally oriented thrust plane using rupture model of Bilham and England (2001). (c, d) Coulomb failure stress change (Δ CFS, in bar) on dextrally slipping Kopili Fault (KF) (~25 km depth) caused by 1897 Shillong Plateau (SP) earthquake

crustal motions are observed by GPS measurements in case of Southeast Asia (Fu et al. 2013) (Fig. 8). However, there are some discrepancies between the GRACE and GPS observations in terms of amplitude and phase of seasonal transients at a few sites in southwest Nepal and Kumaun-Garhwal Himalaya due to local effects of mountain valley, hydrology, groundwater irrigation, and reservoir impoundments (Fu et al. 2013; Panda et al. 2018b; Gahalaut et al. 2017; Gautam et al. 2017).

Hydrological load over Southeast Asia, which is the second largest one after the Amazon basin, lies close and above the Himalayan plate boundary region and may significantly influence the tectonic process along it (Fig. 8). However, the interaction between seasonally induced non-tectonic and tectonic deformation along it remains debated. Panda et al. (2018b) proposed that tectonic deformation along this plate boundary can be significantly influenced by the deformation induced by the non-tectonic hydrological loading cycles. They reported substantially higher transient displacements

in GPS time series that are located above the base of the seismogenic zone, i.e., mid-crustal ramp on the MHT (Panda et al. 2018b). Such higher seasonal transients in the GPS time series indicate change in aseismic slip rate (or slow-slip) on the deep megathrust that may be controlled by seasonal hydrological loading (Panda et al. 2018b). Further, they invoked the fault resonance process in order to explain the higher transient slip at the base of the seismogenic zone (i.e., mid-crustal ramp). It appeared that slip velocity perturbation is several folds higher on the mid-crustal ramp than on the flat during hydrological loading episodes. This suggests that the Himalayan ramp is more sensitive to seasonal modulation than the updip flat segment. Therefore, micro-seismicity and abnormally higher transient in GPS displacement are favored near the transition from velocity-weakening to velocity-strengthening behavior at the base of the Himalayan seismogenic zone (i.e., on the mid-crustal ramp), which are modulated by the seasonal stress changes (Panda et al. 2018b).

Earthquakes in the Himalaya, Fig. 8 Seasonal deformation of Southeast Asia and its influence over tectonic deformation and seismicity along the Himalaya. (After Panda et al. 2018b). (a) Global seasonal mass variation of equivalent water height (EWH, in cm) measured by GRACE. (b) Average peak-to-peak annual surface load variations over Southeast Asia, in terms of equivalent water height (EWH, in mm)

measured by GRACE for the period 2002–2012. (c) Small inset represents detrended GPS time series (north component) of five representative sites from China and India. (d) Correlation between equivalent water height (EWH), rainfall, GPS displacement, and different seismicity catalogues

Human-Induced Deformation

Although, mechanism of faulting and earthquake occurrence process along the Himalayan arc is predominantly tectonically driven process, it has been suggested that the anthropogenic crustal (un-)loading process can also drive long-term fault slip or modulate seismicity (Kundu et al. 2015). In fact, in the past few decades' identification of human-induced earthquakes and associated deformation have become focal points in sociopolitical and scientific discussion (Gonzalez et al. 2012; Kundu et al. 2015; Foulger et al. 2017). More than 700 cases have been documented in the human-induced earthquake database, HiQuake (Foulger et al. 2017; Wilson et al. 2017) and the 25 April 2015, M7.8 Gorkha earthquake, Nepal too has been considered as a human-induced earthquake in that database (Kundu et al. 2015). Using Gravity Recovery and Climate Experiment data and hydrological models, Kundu et al. (2015) have claimed that the thrust earthquakes on the Main Himalayan Thrust (MHT), including the 2015 Mw 7.8 Gorkha, Nepal earthquake, are probably influenced by the steady decline of annual groundwater level over the Indo-Gangetic plain at the rate of rate of $17.7 \pm 4.5 \text{ km}^3/\text{yr}$ over the Indian states of Rajasthan, Punjab, and Haryana (Rodell et al. 2009) (Fig. 9).

Impoundments of reservoir for hydropower production, due to its substantial volume and associated water load-induced deformation (mechanical reservoir load and pore-elastic diffusion process), can also significantly alter the stress regime of critically stressed faults system in the vicinity. They have been considered to have triggered strong earthquakes. The impoundment of Lake Mead and Hoover dam near Boulder City, Nevada, in 1935 and the seismicity in its vicinity is probably the first reported case of reservoir-triggered seismicity (RTS), and since then several cases have been reported worldwide (Gupta 1992). However, no

reservoir-triggered seismicity has been reported so far from the Himalayan region, which consists of at least nine reservoirs. However, theoretical study (Chander and Kalpna 1996) indicates that even a thrust fault can be destabilized by the impoundment of reservoir and the possibility of RTS cannot be ruled out completely from the Himalaya. Recently, a new promising case of reservoir triggered seismicity of the Garhwal region of NW Himalaya, influenced by Tehri reservoir load has been reported (Gahalaut et al. 2017, 2018a). Combined GPS and InSAR measurements indicate that the seasonal water level variations in the Tehri reservoir cause crustal deformation (Gahalaut et al. 2017). Precisely relocated small earthquakes in the Garhwal region, reservoir water level variation at the dam site, and simulation of reservoir-induced stress incorporating pore-pressure diffusion confirm that it is yet another case of RTS in an active thrust faulting environments of the NW-Himalaya (Gahalaut et al. 2018b).

Future Directions: Key Questions to Be Answered

Spatiotemporal variations in seismicity and crustal deformation along the Himalayan arc and adjacent domains are primarily controlled by variation in convergence rate, lithology, rheological properties, thermal structure, topographic features, and structural aspect between the two plates (Gahalaut and Kundu 2012; Arora et al. 2008). Spatiotemporal variations in the mid-crustal seismicity production and crustal movements occur on annual, seasonal, or diurnal basis and can be induced by monsoon, ice-snow load, atmospheric pressure, tidal loading, continental water storage and its fluctuation, and anthropogenic process (Blewitt et al. 2001; Bettinelli et al. 2008; Flouzat et al. 2009; Chanard et al.

Earthquakes in the Himalaya, Fig. 9 Schematic diagram representing the effect of unloading (by anthropogenic groundwater loss) in the Indo-Gangetic plains on the MHT (Bettinelli et al. 2008; Kundu et al. 2015). Crustal unloading in the Indo-Gangetic plains will induce some component of horizontal compression (red arrows) that

adds to the secular interseismic contraction (black arrows) at seismogenic depth on the MHT. Red star represents hypocenter of the 2015 Gorkha, Nepal earthquake and the associated rupture is shown by the pink line along the MHT. (After Kundu et al. 2015)

2014; Ellsworth 2013). Specifically, the regional loading process along the Himalayan arc and adjacent Indo-Ganga plains are complicated by several factors and quantification of tectonic vs. non-tectonic deformation process in the Himalayan arc and adjacent region is a challenge.

Displacement time series observed by the continuous Global Positioning System (cGPS) have revealed that surface load fluctuation can induce surface strain (Wahr et al. 2013; Heki 2004; Bevis et al. 2005; van Dam et al. 2007; Amos et al. 2014). A significant variation of surface loading can be the result of various processes, which influence the seismicity (see above). All of these processes cause the earth lithosphere to deform and can induce significant surface strain. Therefore, cGPS measurements for surface deformation can be used as a proxy for surficial mass distribution. Seasonal hydrological effects are the main candidates for global mass fluctuation process and cause periodic crustal deformation (Bevis et al. 2005; van Dam et al. 2007). In addition, space geodetic techniques can quantify the surface hydrological mass fluctuation with the Gravity Recovery and Climate experiment (GRACE). cGPS-derived vertical seasonal fluctuation have been investigated extensively and compared with GRACE-derived seasonal loading deformation (Fu et al. 2013). Strong seasonal variations of horizontal and vertical components are noticed on cGPS time series in elastic response to heavy rain fall and monsoonal variation in Southeast Asia.

The regional loading process along the Himalayan arc and adjacent Indo-Ganga plains are complicated by several factors. The phase relationship of loading to precipitation is not simple, as suggested by many authors (Wahr et al. 2013; Fu et al. 2013). For the Amazon basin, much of the water mass there is temporarily absorbed into groundwater, which delays its transport out of the system (in the Amazon, by as much as 3 months). GRACE data may also be difficult to relate directly to the cGPS observations, because it averages over such large scale that we could not be able to distinguish between northward accumulating mass and southward mass-transit.

Therefore, in future, we must focus on the nature of deformation process along the Himalayan arc and adjacent Indo-Ganga plains region through the combined geodetic and seismic measurements with the following key objectives (Fig. 8):

1. Understand the role of the Indo-Ganga plains (i.e., surface hydrological load) in the Himalayan deformation process and mid-crustal seismicity generation.
2. Understand the complicated nature of Himalayan loading process (e.g., orographic effect, monsoonal effect, river transportation effect, and flexural effect due to surface hydrological variation in the Indo-Ganga plains).
3. How can we separate the non-tectonic signals from the geodetic and seismic observations? It will also help us to

understand the effect of strong seasonal effects on the cGPS and seismic time series.

4. Does the MHT experience tremor and slow-slip events? Does it get modulated by climatic load? How does the slow-slip event affect the adjacent locked mega-thrust zones?

The explorations of these questions will help us in understanding the earthquake occurrence and deformation process, slip rate, recurrence interval of mega-thrust earthquakes, and strain budget along the Himalayan arc region.

Earthquakes on Oceanic Transform Faults, Unexpectedly Large

Shamita Das

Department of Earth Sciences, University of Oxford, Oxford, UK

Definition

Transform faults are conservative plate boundaries, where material is neither created nor destroyed. The most prominent of these worldwide are oceanic transform faults such as the mid-ocean ridges.

Introduction

One of the key pieces of evidence that supported the theory of plate tectonics in the 1960s was the explanation of how plates move along mid-oceanic transform faults (Wilson 1965). The six possible types of dextral (right-lateral) transform faults are shown in Fig. 1a. Six sinistral (left-lateral) transform faults, which are mirror images of the ones plotted, also can exist. The appearance of the right-lateral systems after a period of growth is shown in Fig. 1b. Note that length of the active transform fault is growing in three cases, decreasing in one case, and indeterminate in two cases, as indicated in Fig. 1b.

The most common transform fault has a ridge-ridge configuration (see Fig. 1a top left-most), in which the oceanic transform fault is bounded at both ends by spreading ridges, with the portion of the previously active transform fault beyond the ridges, called “fracture zones” being practically aseismic. A beautiful example of such transform faults is seen along the Mid-Atlantic ridge. In regions where the spreading ridge is no longer active, the fracture zones are termed “fossil fracture zones.”

Explanation of the focal mechanisms along the ridge and transform faults along mid-ocean ridges was first given by Sykes (1967), and a schematic is shown in Fig. 2. Very occasionally earthquakes do occur on the fracture zone, and have focal mechanisms with reversed polarity from the nearby oceanic transform fault (Engeln et al. 1986). This very useful fact can be used to identify such earthquakes.

Earthquakes on Oceanic Transform Faults, Unexpectedly Large, Fig. 1

(a) Illustration of the six kinds of right-lateral transform faults, with well-known examples indicated on some more common ones. The three kinds of such faults that can have faulting on conjugate planes are located inside the box indicated by the green dashed lines. These are mainly discussed here. Three other possible transform faulting settings are also shown, for completeness. (b) The same as (a) but after some period of growth

Figure 2 also shows that the situation is even more complex with other kinds of mechanisms occurring at the “inner corners.”

That fracture zones are essentially aseismic can be seen by examining earthquakes large enough to have a centroid moment-tensor solution (CMT can be accessed at [http://](http://www.globalcmt.org/CMTsearch.html)

www.globalcmt.org/CMTsearch.html). By counting such earthquakes located within ~1000 km of (as an example) the Mid-Atlantic Ridge between the Equator and 70°N (just north of Iceland), for the 34 year period from 1976 to 2009 inclusive, Robinson (2011) showed that of the 1002 CMT solutions reported, 266 are strike-slip. Of these 266, only 8 are

Earthquakes on Oceanic Transform Faults, Unexpectedly Large,

Fig. 2 Schematic representation of the classical picture at mid-ocean (spreading) ridges, showing the focal mechanisms. Black arrows indicate relative plate motions and red lines the active plate boundary. The red focal mechanism shows the typical ones expected on the (active) transform fault, and the purple ones the typical ones on the spreading ridges. The dashed blue lines are the continuations of the transform fault that are usually visible in bathymetric surveys of the seafloor. The blue focal mechanisms are the ones for the rare earthquakes on these and have strike-slip mechanism reverse to that on the active transform. Both strike-slip and thrust earthquakes are seen in the inner corners and are in green

unambiguously identified as having occurred on the fracture zone by virtue of having focal mechanisms with reversed polarity relative to the nearest transform fault. These rare fracture zone earthquakes had negligible seismic moment compared to the strike-slip earthquakes on the nearby transform faults.

Several unusual cases of large or great earthquakes on oceanic transform faults, including a M_w 8.1 on a fossil fracture zone and a M_w 8.0 pure strike-slip earthquake, which are nearly normal to the existing oceanic transform faults (i.e., fractures along the preexisting ridge fabric) as well as several large mid-oceanic earthquakes with simultaneous conjugate faulting have occurred in the last ≈ 30 years. Table 1 lists all such earthquakes, showing that though the classical theory of plate tectonics says that oceanic transform faults do not usually have “large” or “great” earthquakes, they do occur both on the active transform, on the fracture zone, and, in one case, even on a fossil fracture zone.

The major features of the earthquakes are summarized in Table 1. For a more detailed description of some of these earthquakes, with color figures showing the tectonic settings and rupture processes, see Das (2019). These earthquakes suggest that the oceanic lithosphere is breaking up along the ridge-transform conjugate fault systems under tectonic stresses, that is, the oceanic plates are not rigid as was believed in the early days of plate tectonics.

Rupture on Conjugate Faults in an Oceanic Setting

The intra-plate oceanic sequence of the 1987–1992 Gulf of Alaska earthquakes occurred in a region with no known earthquakes since 1964. The first one occurred on an E-W trending fault (Pegler and Das 1996), with the second one, the largest of the sequence, having its epicenter near the eastern end of the fault zone of the first one. However, its rupture occurred on a N-S trending fault plane. The third one occurred at the southern end of the fault of the second one. Pegler and Das (1996) identified the plane of rupture as having the same N-S trend as the second one. The last, and smallest, earthquake of the sequence occurred at the southernmost end of the N-S fault mentioned above. The aftershocks of the second and third earthquakes, in addition to lying on the main N-S fault plane, activated aftershocks on nearly conjugate NE and SW planes. Using body-wave analysis, magnetic anomaly, and bathymetric data, Pegler and Das (1996) interpreted the sequence as reactivation of preexisting nearly conjugate planes of weakness, related to a fossil ridge-transform system of faults, on the Pacific plate near where it subducts under Alaska. The 2018 Gulf of Alaska earthquake occurred to the west of this sequence, and shows a cross-hatched pattern (United States Geological Survey website) similar to the 1987–1992 sequence, again suggesting a similar interpretation.

The great 1989 Macquarie Ridge earthquake was studied by Das (1992, 1993) using body-wave analysis and the

Earthquakes on Oceanic Transform Faults, Unexpectedly Large, Table 1 Significant earthquakes on oceanic transform faults

	Date (month/day/year)	Location	M_w	Faulting mode
1.	1987–1992	Gulf of Alaska	7.2, 7.8, 7.7, 6.8	Conjugate faults
2.	05/23/1989	Macquarie Ridge	8.2	Conjugate fault was reactivated by aftershocks
3.	03/25/1998	Antarctic Plate	8.0	Cuts across preexisting ridge fabric
4.	06/18/2000	Wharton Basin	7.8	Simultaneous rupture on transform fault and ridge fabric
5.	12/23/2004	Tasman Sea	8.1	Great earthquake on a fossil fracture
6.	04/11/2012	Wharton Basin	8.6, 8.2	Same as 4
7.	01/23/2018	Gulf of Alaska	7.9	Conjugate faults reactivated by aftershocks

inversion technique of Das and Kostrov (see Das (2020), for details of the method). It was shown that the main shock reactivated a dormant conjugate fault, which is seen in the local bathymetry and magnetic anomaly data.

Rupture on a Fault Normal to the Preexisting Zones of Weakness

At the time of its occurrence, the great 1998 Antarctic Plate earthquake was the largest crustal submarine strike-slip earthquake ever recorded. It took place in a region where no seismicity has previously been recorded and was the largest known on the entire Antarctic Plate. Its occurrence is still puzzling as its rupture zone does not coincide with any known feature on the ocean floor, all of which are nearly N-S trending in this region. Even more puzzling, the rupture is nearly E-W trending and actually cuts across these features at right angles, that is, close to the ridge fabric (Henry et al. 2000). A full discussion on the rupture of this earthquake is given by Das (2020, this encyclopedia).

Simultaneous Earthquake Rupture on Conjugate Faults in an Oceanic Setting

The 2000 Wharton Basin earthquake was the first such example known to us. Analysis of broadband teleseismic data and relocated seismicity was used by Robinson et al. (2001) to show that this intraplate earthquake, in the region of diffuse deformation separating the Indian and Australian plates, consisted of two subevents that simultaneously ruptured two near-conjugate planes. This mode of rupture accommodates shortening by a mechanism different from that previously known elsewhere in the region. The larger subevent occurred on a N-S fossil fracture zone, with a relatively high stress drop of about 20 megapascals, showing that large stresses can accumulate in such regions of distributed deformation. The second sub-earthquake occurred on the E-W preexisting ridge fabric. The twin 2012 Wharton Basin earthquakes in a nearby region may have behaved in a similar way, with simultaneous rupture on multiple conjugate planes (Meng et al. 2012).

A Great Earthquake on a Fossil Fracture Zone

Reactivation of fossil fracture zones by nearby large earthquakes had generally been found to produce earthquakes of smaller magnitudes ($M_w < 6$), as shown earlier in the entry. So the M_w 8.0 2004 South Tasman Sea earthquake, away from the Australia-Pacific plate boundary, was very surprising. It was also the fifth largest strike-slip earthquake worldwide since 1900 (see Table 1 of Robinson 2011), to which 2012 M_w 8.6 Sumatra earthquake of Table 1 of this entry now needs to be appended at the top). Inversion of broad-band P- and SH-wave data (Robinson 2011) showed that rupture occurred on a curved fault, with differing strike, slip, and rake on the portions lying to the north and south of the epicenter. The occurrence of this earthquake shows that dead fracture zones can be reactivated in regions of very complex tectonic history with large internal deformation of the plate, to produce stresses required to generate great earthquakes.

Summary

In the classical theory of plate tectonics, oceanic transform faults do not usually have large earthquakes. However, the recent record of the occurrence of several such earthquakes shows that it does. Some of these earthquakes have fractured both conjugate nodal planes. Others have occurred on the fracture zone, and one on a fossil fracture zone. This shows that the oceanic crust is crumbling by fracture of nearly normal conjugate fault planes – the old planes of weakness being related to the ridge fabric and transform faults – even in regions where the transform fault is no longer active. Clearly oceanic plates are not as rigid as was believed in the early days of plate tectonics.

Earthquakes, Did You Feel It?

David J. Wald, Vincent Quitoriano and James W. Dewey
U.S. Geological Survey, Denver Federal Center, Lakewood,
CO, USA

Definition and Introduction

The US Geological Survey (USGS) “Did You Feel It?”[®] (DYFI) system is an automated system for rapidly collecting macroseismic intensity data from Internet users’ shaking and damage reports and generating intensity maps immediately following earthquakes.

Although the collection and assignment of DYFI-based Macroscopic Intensity (MI) data depart from traditional assignments, they are made more quickly, provide more complete coverage at higher spatial resolution, offer citizen input and interaction, and allow data collection at rates and quantities that were not previously possible. These aspects of Internet-based data collection, in turn, allow for data analyses, graphics, and ways to communicate with the public, opportunities that were not feasible with traditional data-collection approaches. DYFI decimal MI assignments are based on regression against traditional MI, and geocoding allows for

spatial averaging; both of these strategies facilitate quantitative data analyses. DYFI can be found online at the website <http://earthquake.usgs.gov/dyfi/>.

Historical Context

Over the past two decades, the DYFI system has collected shaking and damage reports from Internet users immediately following earthquakes. The USGS has been operating DYFI since 1999 in California, since the early 2000s for the rest of the USA, and since the mid-2000s globally (Wald et al. 2011). DYFI has become vital for collecting macroseismic data for all felt seismic events in the USA, and it is also one of the most popular interactive websites within the Federal Government. For earthquakes occurring outside the USA, the worldwide DYFI data rapidly indicate or confirm earthquake occurrence for seismic analysts and scientists at the USGS National Earthquake Information Center (NEIC), giving a quick indication of the occurrence, extent, and nature of shaking effects. The global intensity data from DYFI, and in some cases its international counterparts, can be automatically used as constraints in the USGS ShakeMap system (Wald et al. 1999b), which is the hazard input for the USGS Prompt Assessment of Global Earthquakes for Response system (PAGER, Wald et al. 2006). USGS also allows users who experienced older events to enter DYFI questionnaire responses for important events such as the 1994 Northridge and 1989 Loma Prieta, California, earthquakes via the DYFI Web portal and earthquake archives.

Traditionally, intensities are assigned integer values by a classification process or, less frequently, a range of integer values such as “6–7” or “>6” for less-certain assignments (Musson et al. 2010). The DYFI process of assigning numerical values to macroseismic observations and then calculating real-valued intensities thus represents a philosophical as well as a procedural departure from traditional intensity-assigning methods. Over the years, analyses of the DYFI data strongly suggest that assigning intensities at higher precision is warranted (e.g., Atkinson and Wald 2007; Wald et al. 2011). USGS DYFI and ShakeMap intensities are now precise to one decimal place, and the discrete (I–X) intensity scale is replaced with a continuous, real-valued, scale. When DYFI and similar decimal intensities are plotted as a function of distance, the retention of information to tenths of an intensity unit results in lower scatter than is the case when intensities are assigned by classification and reported to the nearest integer (Wald et al. 2011). For map representation of DYFI decimal intensities, a continuous palette of colors is chosen using algorithms that automatically interpolate between discrete color values, using a similar technique to the one used by ShakeMap (Wald et al. 1999b). This allows us to present more subtle variations of intensity than previously achievable.

The evolution from manual/postal, to emailed, to Web-based macroseismic surveys has been accomplished in many regions of the world. Many countries either maintain the manual approach as the primary strategy or reserve the option to augment their web-based approaches with traditional assignments. Several very successful Internet-based macroseismic survey systems are now implemented in many countries or regions (see summaries in Wald et al. 2011; Goded et al. 2018).

The DYFI System

The DYFI software is fully open source, written in Python, and available publicly through GitHub. Incoming entries from multiple web servers are processed and aggregated over both 1-km and 10-km geocoded boxes for each earthquake and are then used to make interactive event page maps and plots (Fig. 1). A natural challenge with a system such as DYFI is accommodating the post-earthquake deluge of input data and Web traffic. As DYFI has grown in popularity, the USGS has continuously improved capacity via both hardware and software improvements in order to handle the spike in Internet traffic following a widely felt earthquake. While new

responses come in continuously, the backend processes only refresh the online maps every 5 min to ensure that products are updated and transferred to the web before a new run begins. Response rate of DYFI report entries for the 2014 M6.0 South Napa, California, earthquake are shown in Fig. 2. Nearly 26,000 were received within the first hour and a total of 44,000 were ultimately received. Typically, about 60–90% of the entries are received within the first hour of an earthquake. For the largest earthquakes, response times peak at more than 30 responses per second. Figure 3 provides an indication of the variability of the data and its distribution with distance from the epicenter.

Data for widely felt earthquakes come in at a rate that allows confirmation of the earthquake’s occurrence within minutes. The DYFI maps evolve rapidly to informative macroseismic intensity distributions that are useful to the public, media, scientists, and even emergency managers, typically within tens of minutes. Statistics attest to the abundance and rapid availability of these Internet-based macroseismic data: nearly five million entries have been amassed over two decades, there are 64 events with more than 10,000 responses, and 550 events have over 1000 entries. The greatest number of responses for an earthquake is more than 146,000, for the 2011 M5.8 Mineral, Virginia event, which was felt by more

Earthquakes, Did You Feel It?, Fig. 1 Interactive map from the USGS event web pages for the 2014 magnitude 6.0 South Napa Valley, California, earthquake. DYFI data are displayed in 1-km square boxes color-coded to

the inset legend used by DYFI and ShakeMap to show the community decimal intensity (Wald et al. 2011). Independently derived ShakeMap intensity contours and seismic stations (triangles) are shown for comparison

Earthquakes, Did You Feel It?,

Fig. 2 Response rate of DYFI report entries for the M6.0 South Napa earthquake

Earthquakes, Did You Feel It?,

Fig. 3 Plot of intensity versus distance from the epicenter for the M6.0 South Napa earthquake. The colored line is the predicted intensities based on the equations of Atkinson and Wald 2007, for magnitude 6.0. Small circles are individual geocode box intensity values; larger circles are averages over distance bins equal in log space

Americans than any other in history. Questionnaire response rates have reached 62,000 per hour (approx. 1000 per min) for another event, requiring substantial web resource allocation and capacity.

Citizen Science Seismology

The DYFI portal provides a two-way information conduit, since citizens coming to the USGS for information are empowered to become data providers themselves by contributing valuable observations that benefit the USGS as well as the observers, their local communities, and earthquake responders. DYFI also provides an important human perspective on earthquakes, providing sociological documentation of

the way people behave and respond, and how they perceive risk (e.g., Celsi et al. 2005). DYFI also seems to provide emotional help to citizens who have just had a frightening or even traumatic experience, by allowing citizens to share their experiences and enabling them to contribute their observations towards a general public understanding of the phenomenon they have experienced, DYFI provides many with a form of catharsis at an opportune time, and in a rapid fashion. Often users describe the desire to confirm their experience with others, or in the case of DYFI, with the collective community. The DYFI system also educates the public on oft-misunderstood seismological concepts like the spatial variations of shaking intensity, and it provides a basis for understanding the difference between macroseismic intensity and instrumental magnitude.

Earthquakes, Did You Feel It?, Fig. 4 Cumulative maximum DYFI intensities, 10-km geocoded, in the USA from 1999 to 2018. The same intensity color-coding is used as in Fig. 1

With two decades of DYFI reports, we can now map out the maximum intensity of shaking reported over the entire U.S. during that time period (Fig. 4). With DYFI, nearly every felt earthquake in the USA is or can be reported now. Thus, this map represents an extraordinary contribution of the DYFI system and something we have never been able to show before: the actual distribution of shaking intensity over the entire nation for nearly two decades. One can further examine the overall extent and intensity of DYFI contributions nationwide on the interactive DYFI cumulative and annual summary maps provided on a separate USGS ArcGIS platform link found on the USGS DYFI homepage. These data have been particularly useful in determining the level and extent of shaking for induced earthquakes in the Central USA (Fig. 4). The DYFI induced database has over 200,000 observations in the past decade with 22,000 at distances less than 20 km; we provide individual responses and aggregated event-associated intensities in 1-km and 10-km boxes. The data are available online in USGS ScienceBase data archives (<https://doi.org/10.5066/F7WM1BPC>).

Scientifically, DYFI data have been widely utilized in seismological and earthquake engineering studies (for a partial summary, see Wald et al. 2011). For example, Worden et al. (2012) employed DYFI data to derive new relations among peak ground motion parameters and intensity data.

The development of these relations sets a new standard for ground-motion-to-intensity relations in that the DYFI intensity data used are decimal intensities and reverse relations are provided. Similarly, DYFI data have recently been used to derive direct intensity prediction equations or IPEs (e.g., Atkinson and Wald 2007); these equations are important for robust ShakeMap generation (Worden et al. 2018) and hazard evaluations from historical macroseismic observations, as well as for improved DYFI filtering. DYFI data have been widely used in attempts to distinguish shaking levels expected from induced earthquakes from naturally occurring ones (e.g., Atkinson et al. 2018).

Outlook

DYFI data have been made accessible via the NEIC's ComCat earthquake archives and database. Users can now replicate, filter, and update MI datasets via USGS web services, though of course individual responses are not accessible given that they contain personally identifiable information (PII). Ongoing DYFI developments include voice activated (smart-speaker) response entries and an open API for third-party entries. Further, since higher macroseismic intensity values (typically, VIII and greater) primarily describe

observed structural damage to buildings (e.g., Musson et al. 2010), and the usual DYFI contributor generally lacks the necessary engineering expertise, one could argue that assigning intensities to intensity VIII and higher should be done formally by professionals. We are investigating ways to augment DYFI at these higher intensities by using crowd-source engineering experience for events that have damage, though nearly 95% of our data collection is at intensity 6 and lower. Likewise, efforts are ongoing to employ more uniform data collection strategies, with the goal of harmonizing data collection around the globe (e.g., Goded et al. 2018).

Earthquakes, Early and Strong Motion Warning

Richard M. Allen

Berkeley Seismological Laboratory, Department of Earth and Planetary Science, University of California, Berkeley, CA, USA

Synopsis

Strong motion earthquake warning (also known as earthquake early warning) is the rapid detection of an earthquake underway, the estimation of the ground shaking likely to result, and the issuance of an alert to people in the region where the ground shaking is likely to be hazardous. The last decade has seen rapid development of methodologies for early warning, which include the use of strong motion observations close to the epicenter to provide warnings at greater distances, the use of P-wave observations across a network to locate the event and map the distribution of likely strong ground motion, and the use of a P-wave detection at a single station to estimate the likely shaking intensity at the same station. These approaches have been listed in the order of increasing warning time, but the additional warning time comes at the expense of certainty. The earlier a warning is provided the greater the likelihood of false and missed alarms and the greater the uncertainty in the estimated shaking intensity. Typical warning times range from a few seconds to tens of seconds; the upper limit is about 1 min. Identified applications include personal protective measures where individuals move to a safe-zone within a few feet; automated mechanical response including stopping trains and isolating sensitive and hazardous machinery and chemicals; and situation awareness by large organizations that can help prevent cascading failures and be available before shaking disrupts communications. Large-scale public warning systems are currently operational in Mexico and Japan, and smaller systems are used in Romania, Turkey, and Taiwan. Testing is underway by seismic networks in many other countries; however, implementation will require significant financial, political, and sociological hurdles to be crossed.

Introduction

Strong motion earthquake warning, more commonly referred to as earthquake early warning (EEW), is the rapid detection of an earthquake underway, estimation of the intensity of ground shaking likely to result, and issuance of a warning in the area likely to experience damaging strong motion. It provides high-probability warnings of shaking likely to occur

within seconds to tens of seconds. The ability to provide warnings is relatively new and due to recent scientific development of methodologies to rapidly estimate the size of earthquakes underway, coupled with modern engineering of rapid communications to collect seismic data and distribute warnings, and a political will to operate state-of-the-art geophysical networks for the purpose of both scientific discovery and societal benefit.

EEW is one of three categories of earthquake warnings. Long-term warnings provide relatively low probabilities of earthquakes over long time periods, typically decades, and are usually referred to as earthquake forecasts. On these long timescales, earthquake likelihood can be estimated based on historic earthquake recurrence intervals and plate motion rates, linked together with deformation models incorporating fault geometries. For example, the probability of an $M > 6.7$ earthquake on the Hayward-Rodgers Creek fault that crosses the UC Berkeley campus is estimated to be 31% over 30 years (Working Group on California Earthquake Probabilities 2007). These forecasts are also translated into estimates of ground shaking intensity that can be used to define building codes designed to prevent new buildings from collapse in the forecast of earthquakes.

The other end-member is earthquake prediction. The term prediction usually means a high probability of a large, damaging earthquake over a short time interval. For example, predicting an $M > 7$ earthquake on the Hayward Fault next week (Allen 1976). Earthquake prediction is currently not possible, as we have not been able to identify a precursory signal that consistently occurs before earthquakes, and most seismologists agree that prediction will not be possible in the near future. EEW is intermediary in that it is possible to provide warning before shaking is felt, however, the warnings are only a few seconds to tens of seconds.

Uses of Early Warning

Uses of EEW that have been identified to date fall into three broad categories (Allen et al. 2009d): personal protection, automated mechanical actions, and situation awareness. The first use that people think about when introduced to early warning is personal protection. For most people, given that there will only be a few to a few tens of seconds of warning, the appropriate action is to move to a “safe-zone” within a few meters of your current location – under a sturdy table, away from falling hazards including windows, bookshelves, etc. These safe-zones need to be identified ahead of time in the locations that people spend most of their time, that is, in their homes and offices or workplaces. In most cases there is not sufficient time to evacuate buildings, and EEW is no substitute for building standards that prevent building collapse. It currently takes schoolchildren in Japan and Mexico

~5 s to get under their desks in response to audible warnings. Outdoors, people should move away from buildings, masonry walls, and other falling hazards including broken glass, street signs, etc. In hazardous work sites including construction sites, manufacturing and chemical facilities, the same principle applies: move to predefined safe-zones.

The second category is automated mechanical control. Within the transportation sector, implemented warning systems are currently used to slow and stop trains, stop airplanes from landing by issuing a go-around command, and to bring traffic to a halt. They could also be used to turn metering or tollbooth lights to red at the entrance to vulnerable road bridges, tunnels, and overpasses. Within buildings, warnings are now used to stop elevators at the next floor and open the doors, open emergency exit doors and window blinds, and turn on lights. Industrial facilities use the warning to place machinery or product into a safe mode. For example, a chip manufacturer in Japan places sensitive micro-robots into a hold mode to reduce damage, and isolates hazardous chemical systems to minimize any resulting leaks. In Japan, engineers are also experimenting with using warnings within automated structural control systems that change the mechanical properties of the building to better withstand the expected shaking. This is an area where there are a myriad of possible applications, most of which are very specific to individual users.

Finally, situation awareness is very important to organizations with responsibilities for large infrastructures and/or people. These include government agencies, utility, and transportation companies. While these groups may take early warning actions, they also have a need to rapidly understand why part or all of their system is failing. For example, an electrical power grid may start to fail in one area, and operators need to rapidly understand why it is failing in order to reduce cascading failures throughout the system. EEW can provide this information more rapidly than any of the existing post-earthquake information systems. EEW also has the advantage that much of the data needed to map out the likely shaking is collected before significant shaking has occurred. This means that the information can be transmitted across data-networks and out to users before strong shaking has the opportunity to disrupt communications.

One of the main concerns expressed in response to the early warning concept is panic: will people panic when they receive the warning and injure themselves or others as a result. Social scientists have long studied this issue and find that it is not the source of concern that many seismologists think it is (Quarantelli 1956; Goltz 2002). The experience that we now have from public warnings in Mexico and Japan provides no evidence that warnings result in panic (Espinosa Aranda et al. 2009; Kamigaichi et al. 2009). There is no evidence for traffic accidents resulting from warnings and no evidence of public stampedes. Implementation of EEW does require an educational campaign to educate

people about what EEW can do and help them identify the appropriate actions in their locations (Kamigaichi et al. 2009).

Approaches to Early Warning

All EEW methodologies must use just a few seconds of data to detect an earthquake underway and rapidly assess its intensity. There is generally a trade-off between the amount of warning time and the accuracy or certainty of the warnings. Greater certainty requires more data from one or more stations, but waiting for that data reduces the warning time. The challenge when building an early warning system is to determine whether additional accuracy is worth the increasing delay.

Strong-motion-based warning The first warning methodologies used this approach. When strong ground shaking is observed at one location, close to the earthquake epicenter, the shaking intensity at greater distances can be estimated using ground motion prediction equations and a warning transmitted ahead of the ground shaking. This approach is called front detection and is used in Mexico City where the earthquake source zone is ~300 km from the city. Figure 1 shows the time at which peak ground shaking was observed at all available stations recording nine $M \geq 6$ earthquakes. A strong-motion-based warning would be possible at some point between 10 s and 20 s after the origin time for these events, depending on the proximity of the closest station(s). By 20 s, the onset of strong shaking is ~60 km from the epicenter meaning that warnings based on peak-shaking observations near the epicenter are only available at distances greater than ~60 km. The region within ~60 km of the epicenter would get no warning and is referred to as the “blind zone.”

P-wave based warning. To reduce the size of the blind zone, P-wave based methodologies are used. These approaches use a few seconds of the P-wave to estimate either the magnitude or the peak-shaking amplitude. In order to estimate the magnitude, a variety of parameters have been developed that are measures of the frequency content (Nakamura 1988; Allen and Kanamori 2003; Kanamori 2005) or the amplitude (Kamigaichi 2004; Wu and Kanamori 2005b; Zollo et al. 2006; Cua and Heaton 2007; Wurman et al. 2007; Böse et al. 2008; Wu and Kanamori 2008b; Köhler et al. 2009). In order to estimate magnitude, amplitude-based parameters need to be corrected for epicentral distance. However, the frequency-based parameters have been found to be insensitive to epicentral distance provided the observations are made within ~100 km of the epicenter. For all of these parameters empirical scaling relations between the observation and earthquake magnitude have been developed so that magnitude (plus or minus some uncertainty) can be estimated from an observation at one or more stations.

Regional warning. When a regional network is available, P-wave based estimates of magnitude can be combined with an estimate of the earthquake location to then map the distribution of strong ground motion using ground motion prediction equations. In their simplest form these maps are a “bullseye” centered on the epicenter. Corrections can also be made for site amplification effects. Examples of this approach include ElarmS (Allen 2007; Wurman et al. 2007; Allen et al. 2009a; Brown et al. 2009), Presto (Zollo et al. 2009), the Virtual Seismologist (Cua and Heaton 2007; Cua et al. 2009), and the NIED approach in Japan (Horiuchi et al. 2005).

When using a regional network, P-wave observations at multiple stations can be combined in order to verify that an earthquake is underway and improve the accuracy of the magnitude estimate. Generally, the more stations used, the better the accuracy of the warnings and the fewer false alarms. The time at which a warning is available therefore depends on the number of station detections required and the number of seconds of P-wave data required at each station. Figure 1 illustrates the amount of warning time available using this approach. The horizontal blue line at 7.6 s represents the time at which a warning is available for a particular scenario (Fig. 1). In this case, the size of the blind zone is ~15 km and the amount of warning time increases linearly with distance beyond 15 km. There would be ~9 s warning at 50 km and ~22 s warning at 100 km.

Onsite warning. Onsite warning provides the most rapid approach to earthquake warning by removing the need for communications. The delay in issuing a warning is minimized by using a seismic station at the location where the warning is needed. Onsite methodologies are intended to estimate the intensity of ground shaking at the same location that the P-wave is detected (Odaka et al. 2003; Wu and Kanamori 2005a, b, 2008a, b; Nakamura and Saita 2007a, b; Wu et al. 2007; Böse et al. 2009a, b). The challenge with onsite warning is to provide enough accuracy that the warnings are useful. The character of P-wave arrivals is variable at different locations for the same earthquake due to variability in source radiation and also local site effects. Using a single station (or several stations within a few hundred meters) does not allow for averaging of this variability as in the case of regional methodologies. However, the onsite approach is faster.

Figure 1 illustrates the best-case scenario for onsite warning in which the warning is available using 1 s of P-wave data and the earthquake is at a sufficient depth that there is more than 1 s between the P-wave arrival and the onset of peak shaking at the epicenter. This means that there is no blind zone and a warning is available at the epicenter. The warning time increases with distance as the time-separation of the P-wave and peak shaking increases. Typical warning times are ~2 s at 10 km, ~7 s at 50 km, and ~12 s at 100 km. The onsite approach provides the most warning close to the epicenter.

Earthquakes, Early and Strong Motion Warning, Fig. 1 Plot showing the time of observed peak shaking for large magnitude events and illustrating the time at which warnings could be available using various methods. The time of peak shaking was determined for all available stations in nine $M \geq 6$ earthquakes from California (triangles, magnitudes 6.0, 6.5, 6.7, 7.1, 7.1, and 7.5) and Japan (circles, magnitudes 7.0, 7.1, and 7.3) and is plotted as a function of epicentral distance. All events are crustal earthquakes with epicentral depths of 21 km or less. The red shaded region illustrates the approximate interval of strong shaking when most of the peak-shaking observations are made. Note that there are few observations close to the epicenter due to the stations spacing of networks in California and Japan. The P-wave (solid black line) and S-wave (dashed black line) arrival times for a 10 km depth earthquake are also shown. The blue line and arrows illustrate available warning times for a regional P-wave based warning system. The horizontal line is the time at which a warning is available. It assumes that the required number of stations for a warning have detected a P-wave once the

P-wave front reaches 25 km (at 4.6 s), that 1 s of P-wave is required to estimate magnitude (available at 5.6 s), and that an additional 2 s is needed for communications. The purpose-built seismic network in Japan provides data to the network centers within 1 s, and we assume that an additional 1 s is required to get the warning out to users. This means that the warning reaches users at 7.6 s after the origin time. The onset of strong shaking has reached ~15 km from the epicenter at this time. The available warning time increases linearly (shown by blue arrows) from 0 s at 15 km to ~22 s at 100 km. The green line and arrows illustrate the available warning time using the onsite P-wave based warning approach. It is assumed that 1 s of P-wave data is needed and the time of warning (green line) is therefore 1 s after the P-wave arrival. As shown, it is possible to provide a warning at the epicenter if the earthquake is more than ~10 km deep meaning there could be no blind zone. The warning time then increases with distance as the time between the P-wave arrival and peak shaking increases. Warning times (green arrows) range from ~2 s at 10 km to ~12 s at 100 km

However, for locations at greater distances, regional warning provides more warning time than onsite warning as alerts are transmitted electronically ahead of ground motion. In the scenarios shown in Fig. 1, the crossover when the regional method provides more warning than onsite is at ~35 km.

Implementations of Early Warning

There are currently two large-scale implementations of early warning in Mexico and Japan (Fig. 2). The first public system started to provide warnings to Mexico City in 1993. It was

Earthquakes, Early and Strong Motion Warning, Fig. 2 Map of seismic hazard around the world (pink represents the greatest hazard) showing regions where earthquake early warnings are currently being

provided (blue labels) and the regions where real-time testing on existing seismic networks is underway (green labels). (After Giardini 1999)

built following the 1985 M8.1 earthquake that killed 10,000 people in the city. The system uses a line of seismometers deployed near the coastline to detect offshore earthquakes and transmit the warning 300 km to the city ahead of strong shaking (Espinosa Aranda et al. 1995). The offset between the source region and the city allows the use of a front detection approach and still provides more than 60 s of warning time. These warnings are broadcast by 58 radio stations and 6 TV channels in the city. There are also more than 250 users who receive the warning through dedicated radio links including schools and universities, emergency and civil protection agencies, government buildings, and the subway system.

Japan Railways first began to experiment with early warning in the 1960s. These systems became increasingly sophisticated including the first P-wave based application of UrEDAS in the 1980s (Nakamura 1988). With the growth of computerized communication systems in the 1990s automated remote sensing of earthquakes expanded. Following the 1995 Kobe earthquake that killed 6,000 people, Japan installed dense seismic networks across the entire country (Okada et al. 2004). This network led to the development and implementation of a nationwide regional warning system that became operational in 2007 and is operated by the Japan Meteorological Agency (JMA). These warnings are now broadcast by the majority of TV and radio stations in Japan, through the government operated J-Alert system that issues warnings to municipalities (many of which relay the

warning to loudspeaker systems in public spaces), by cell phone companies, and by a myriad of private providers and purpose-built consumer devices (Kamigaichi et al. 2009). The various Japanese systems use both onsite and regional warning systems. In the 2004 M_w 7.2 Niigata earthquake the emergency brakes of one of the bullet trains were triggered by the onsite UrEDAS system (Nakamura and Saita 2007a), and the regional warning system operated by JMA has issued warnings for multiple earthquakes including the 2008 M_w 7.2 Iwate-Miyagi Nairiku earthquake (Kamigaichi et al. 2009).

Smaller scale and user-specific warning systems have also been implemented in various locations around the world. In Bucharest, warnings are provided to a nuclear research facility (Ionescu et al. 2007). Istanbul has warning systems for a power plant and a large banking building, and a more general use warning system has also been implemented in the last few years using a new strong motion network (Alcik et al. 2009). In Taipei, a test warning system provided warnings to the rail system, the university, and a hospital (Wu and Teng 2002). Finally, in the US, a temporary warning system was implemented following the 1989 Loma Prieta earthquake (Bakun et al. 1994).

Testing of early warning methodologies is now underway on an increasing number of regional seismic networks around the world. This includes networks in California, China, Italy, at the Pacific Tsunami Warning Center, and in Switzerland (Fig. 2). In many of these cases the technical feasibility of

providing warnings has been demonstrated. Whether these test systems will transition to implementation of public warning systems will therefore be largely determined by financial, political, and sociological factors.

Summary

The last decade has seen rapid development of earthquake early warning methodologies (e.g., Gasparini et al. 2007; Allen et al. 2009b, c) by multiple research groups around the world. A range of methodologies has been developed that generate warnings based on observations of strong shaking near the epicenter, estimation of shaking hazard maps using P-wave detections across a network, and single-station detections of P-waves to estimate hazard at the same location. Warning times typically range from a few seconds to tens of seconds with an upper limit of around 1 min. With all these methodologies there is a trade-off between the accuracy of the warning and the amount of warning time. The challenge is to identify the optimal threshold at which to provide a warning.

There are now several implementations of public warning systems around the world, most notably in Mexico and Japan. These provide insight to the potential uses of earthquake alerts, which fall into three categories. Personal protection is about actions of individuals to protect themselves. For individuals it is important to identify “safe-zones” at home and work. These are spaces that are reachable within a few seconds where they will be protected from falling hazards. Automated mechanical control can be used to further reduce the impacts of earthquakes. This category includes slowing trains, opening elevators at the nearest floor, and isolating sensitive or hazardous machinery or chemicals. Finally, early warning can provide situational awareness information to large organizations that may be used to limit cascading failures and initiate response. This information could be available before much of the shaking, and therefore increases the likelihood that the information can be transmitted before communications are lost.

While 5 years ago there were many technical questions about the feasibility of earthquake early warning, today the primary hurdles to implementation are financial, political, and sociological. The existing public warning systems in Mexico and Japan were built following major destructive earthquakes. The challenge for the hazard mitigation communities in other countries is to generate the necessary will to implement these systems before the next earthquake.

Earthquakes, Energy

Domenico Di Giacomo and Peter Borman (Deceased)
Department 2: Physics of the Earth, GFZ German Research Center for Geosciences, Potsdam, Germany

Definition and Calculation

During the earthquake process, the strain energy W available for rupture is divided into fracture energy E_G , thermal energy E_H , and radiated seismic energy E_S . The stress conditions around the fault and the rheological and elastic characteristics of the Earth materials being ruptured determine the partitioning of the overall energy budget involved in the earthquake source process. In particular, E_G and E_H are the energies dissipated mechanically and as frictional heat during faulting, respectively, and E_S is the energy fraction that goes into elastic seismic waves energy. The latter being of great importance for seismologists in evaluating an earthquake's shaking potential, in the following the relationship between the strain energy and radiated seismic energy is outlined.

After Knopoff (1958), the change in strain energy before and after an earthquake can be obtained from:

$$\Delta W = S \bar{D} \bar{\sigma}, \quad (1)$$

where S = fault area, D = average displacement over the fault, and $\bar{\sigma} = (\sigma_0 + \sigma_1)/2$ is the mean stress (with σ_0 being the initial stress and σ_1 the final one). This energy represents the total work associated to the earthquake rupture process. The small energy fraction converted to E_S is (e.g., Wyss and Molnar 1972):

$$E_S = \frac{1}{2} (\sigma_0 + \sigma_1 - 2\sigma_f) \cdot S \bar{D}, \quad (2)$$

where σ_f is the average frictional stress during faulting. It is also useful to relate E_S and ΔW via the radiation efficiency $\eta_R = E_S/(E_S + E_G)$ (see, e.g., Wyss 1970; Husseini 1977):

$$E_S = \eta_R \Delta W. \quad (3)$$

The radiation efficiency η_R , spanning between 0 and 1, expresses the amount of work dissipated mechanically, therefore if an earthquake is effective in radiating E_S then η_R approaches 1 (that is to say about all the energy budget is converted into the seismic waves energy), whereas if η_R is very small or = 0 then the energy is dissipated and no E_S is radiated.

Assuming that the final stress σ_f and the frictional stress σ_f are identical (that is to say the stress drop $\Delta\sigma = \sigma_0 - \sigma_f$ is complete, Orowan 1960), it has been shown by Kanamori (1977) that a measure of ΔW can be obtained considering another important physical parameter of the seismic source, that is the seismic moment M_0 :

$$\Delta W = \left(\frac{\Delta\sigma}{2\mu} \right) M_0, \quad (4)$$

with $M_0 = \mu S \bar{D}$ (where μ = rigidity of the medium in the source area). M_0 is a measure of the overall static displacement caused by the fault rupture. It is a well determined seismological parameter (normally within a factor of 2) since it must be calculated from long and/or very long periods (usually >100 s for large earthquakes) of the recorded seismograms (Dziwonski et al. 1981), which are less affected than the short periods by the small-scale Earth heterogeneities along the path from the source to the receivers.

By assuming that the stress drop is complete and nearly constant (between some 20 and 60 bars = $2-6 \cdot 10^7$ dyn/cm² = 2–6 MPa) for very large earthquakes and that $\mu = 3-6 \cdot 10^{11}$ dyn/cm² = 3–6 $\cdot 10^4$ MPa in the source area under average crust-upper mantle conditions, Kanamori (1977) showed that the ratio

$$E_S/M_0 = 5 \times 10^{-5} = \text{constant}. \quad (5)$$

Therefore, under these conditions (adopted also for introducing the moment magnitude M_w , see ► “Earthquake, Magnitude”), one could easily have an indirect estimation of E_S from known M_0 .

However, M_0 and E_S are two distinct physical parameters. Indeed, M_0 is a static parameter that is not sensible to the details of the rupture history and does not bring any direct information about the frequency content radiated by the seismic source, whereas E_S depends on the dynamic characteristics of the seismic source and, being related to velocity, it is more important than M_0 for evaluating the earthquake damage potential over frequencies of engineering interest (between about 0.1 and 10 Hz). Therefore, direct and independent measurements of E_S are fundamentals in seismic source studies, also considering that many authors pointed

out how the assumption of constant stress drop may not be fulfilled (see, e.g., Purcaru and Berckhemer 1978). Indeed, E_S is sensible to the stress conditions during the fault rupture, as shown by the following formulation (e.g., Rudnicki and Freund 1981):

$$E_S = \int_{-\infty}^{\infty} \int_S [-\sigma_{ij} \gamma_j \dot{u}_i] dS dt, \quad (6)$$

where $\dot{u}_i$ = particle velocity, σ_{ij} = stress change associated with the fault displacement u_i , γ_j = unit vector normal to the surface S and pointing outward from the source, and t = time. This definition holds in the far field, that is, the radius of the surface S is much larger than the dimension of the earthquake source. It can be shown that Eq. 6 is equivalent to another one often used in seismology and proposed by Haskell (1964):

$$E_S = \int_{-\infty}^{\infty} \int_S \rho [\alpha \dot{u}_\alpha^2 + \beta \dot{u}_\beta^2] dS dt, \quad (7)$$

where ρ = density, α and β = P - and S -wave velocities in the medium, $\dot{u}_\alpha$ and $\dot{u}_\beta$ = far-field velocity records of P - and S -waves, respectively. Thus, it would be straightforward to compute E_S by analyzing the recorded waveforms. However, with respect to the determination of M_0 , for computing E_S it must be considered not only the low-frequency part but especially the high-frequency content of the seismograms, which is more sensible to the fine heterogeneities of the Earth structure. Since the seismic recordings must be corrected for the energy loss due to the geometrical spreading and anelastic attenuation of body waves during their travel from the seismic source to the receivers (see ► “Propagation of Elastic Waves: Fundamentals”), it follows that the computation of E_S is more difficult and less stable than M_0 . However, thanks to the worldwide deployment of high-quality digital broadband seismic station networks in the past few decades, much progress has been done and the calculation of E_S has started on a routine basis. Here a brief description of some techniques to calculate E_S is reported.

Since the correction for the high frequencies (above 1–2 Hz) is difficult to perform, many approaches to compute E_S use teleseismic recordings (usually between 30° and 90° epicentral distance Δ , although some procedure for rapid response purposes uses also recordings down to 20° or 25°, see Newman and Okal 1998; Di Giacomo et al. 2010a) for global earthquakes (magnitude above ~5) so that the effects of the Earth filter can be reasonably modeled by assuming an average 1-D layered structure. Moreover, since the P -waves are less affected by attenuation than S -waves, for which the correction for propagation effects at frequencies $f > 0.5$ Hz

may be difficult on a routine basis, the analysis is often performed (1) by considering the P -wave train of the seismograms and (2) in the frequency domain by exploiting the Parseval's identity:

$$\int_{-\infty}^{\infty} |\hat{s}(\omega)|^2 d\omega = 2\pi \int_{-\infty}^{\infty} |s(t)|^2 dt, \quad (8)$$

where $\hat{s}(\omega)$ is the Fourier transform of the time signal $s(t)$ and $\omega = 2\pi f$ the angular frequency.

Currently E_S determinations at the USGS are obtained from the approach proposed by Boatwright and Choy (1986) and are available at the SOPAR database (<http://neic.usgs.gov/neis/sopar/>). This method calculates the energy flux ε^* from the velocity spectrum of P -waves $|\dot{u}(\omega)|$ as:

$$\varepsilon^* = \frac{\rho\alpha}{\pi} \int_0^{\infty} |\dot{u}(\omega)|^2 e^{(\omega t_x^*(\omega))} d\omega, \quad (9)$$

where the symbol * indicates that the energy flux is corrected for anelastic attenuation by the function $t_x^*(\omega)$ (Choy and Cormier 1986). Then, the computation of the average E_S is obtained from:

$$E_S = 4\pi \langle F \rangle^2 \frac{\sum R_i^2 \varepsilon_i^*}{\sum F_i^2}, \quad (10)$$

where $\langle F \rangle$ is the average radiation pattern coefficient for P -waves over the focal sphere, ε_i^* the energy flux at a given station i , R_i the geometrical spreading, and F_i the specific radiation pattern for the station i (Aki and Richards 1980).

Other authors calculate E_S from integration of the moment rate spectral function (an average theoretical curve is shown in Fig. 8 of the entry ► “Earthquake, Magnitude”). The moment rate spectrum $|\hat{M}(f)|$ can be obtained from the teleseismic P -waves spectrum $|\hat{u}(f)|$ as (e.g., Houston and Kanamori 1986):

$$|\hat{M}(f)| = \frac{4\pi\rho\alpha^3 R_E e^{(\pi f t^*)} |\hat{u}(f)|}{g(\Delta)R(\theta, \phi)C|\hat{I}(f)|}, \quad (11)$$

where, R_E is the Earth radius, $g(\Delta)$ the geometrical spreading factor, $R(\theta, \phi)$ the radiation pattern, C the free surface coefficient, and $|\hat{I}(f)|$ the instrument response. Recalling that E_S is proportional to velocity, and, therefore, to the derivative of the function obtained from Eq. 11, E_S is obtained from integration over frequency f as (see, e.g., Venkataraman and Kanamori 2004):

$$\begin{aligned} E_S &= \left[\frac{8\pi}{15\rho\alpha^5} + \frac{8\pi}{10\rho\beta^5} \right] \int_0^{\infty} f^2 |\hat{M}(f)|^2 df \\ &= \left[\frac{2}{15\pi\rho\alpha^5} + \frac{1}{10\pi\rho\beta^5} \right] \int_0^{\infty} |\hat{\dot{M}}(f)|^2 df, \end{aligned} \quad (12)$$

which holds for point sources, that is, sources smaller than the analyzed wavelengths (see ► “Earthquake Source Theory”) and neglecting directivity effects.

In sum, the calculation of E_S requires, after correction for propagation effects, to integrate the squared velocity spectrum recorded at seismic stations over a broad frequency range. Correction for the propagation effects is one of the most challenging tasks in seismological practice, since – in contrast to seismic moment determination (see ► “Earthquake, Magnitude”) – the high-frequency part of the source spectrum must also be considered. Correcting frequencies >1 Hz requires detailed knowledge of the Earth fine structure and attenuation properties, also below the seismic station, which is often not available. Consequently, E_S determinations from local and/or regional recordings are more problematic and are, anyway, more reliable only in areas with a high density of seismic stations (like California and Japan, see, e.g., the recent works by Izutani and Kanamori 2001; Venkataraman et al. 2002; Boatwright et al. 2002; Oth et al. 2010) where a better knowledge of the local Earth structure is available.

Summary and Outlook

The energy budget involved in the earthquake process is partitioned in different forms. In seismology it is of great importance to quantify two macroscopic parameters of the source, namely the seismic moment M_0 and the radiated seismic energy E_S . While the former (and the related magnitude M_w , see ► “Earthquake, Magnitude”) is a static measure of the seismic source and fundamental for the tsunami potential evaluation of an earthquake, the latter (and the related magnitude M_e) represents the fraction of the strain energy converted in elastic seismic waves energy and fundamental for the evaluation of the shaking potential.

However, only since the early 1990s procedures to calculate E_S can be implemented on a routine basis at regional and global seismological centers. The approach of Boatwright and Choy (1986) allowed systematic and direct measurements of E_S from digital data, and later Choy and Boatwright (1995) demonstrated the importance of such measurements showing the significant variability of E_S for a given value of M_0 . Therefore, the indirect measurement of E_S , based on the assumptions leading to Eq. 5, may be affected by large errors.

Of course, a better picture of the source characteristics can be obtained and help end users in the evaluation of the

tsunami and shaking potential of an earthquake by complementing the information provided by direct measurements of E_S and M_0 and their related magnitudes. To this regard it is remarkable the case of two earthquakes that occurred about 500 km apart from each other in Central America, namely the 1991 Costa Rica earthquake and the 1992 Nicaragua earthquake. Both had the same moment magnitude $M_w = 7.6$ (i.e., about the same M_0). Because of their small difference in epicenter location, one can assume very similar propagation paths to teleseismic stations. However, the broadband waveforms of both earthquakes, recorded at identical stations, differ strongly. As an example, Fig. 1 illustrates the P -wave windows, their time-frequency analysis performed with the S -transform (Stockwell et al. 1996), and the corresponding E_S - Me (see Di Giacomo et al. 2010a, b) values at station CCM for both earthquakes. The 1991 Costa Rica earthquake has much larger amplitudes, especially at higher frequencies, than the 1992 Nicaragua event. Such large differences can be only ascribed to significant

differences in the medium-to-high-frequency parts of the source spectra of these two earthquakes with about the same M_0 . Accordingly, E_S (and the corresponding Me) for the Costa Rica earthquake is much larger than for the Nicaragua earthquake. The latter caused a damaging *Tsunami* with 8 m run-up height, in contrast to severe damages caused by strong ground shaking of *intensity* I = X in the epicentral area of the Costa Rica earthquake (see ► “Earthquakes, Intensity”). This shows that M_0 alone (and a single type of magnitude as M_w) may not describe accurately enough the kind of seismic hazard and damage potential posed by a given earthquake and that a combined use of M_0 and E_S (and a multiple magnitude approach, see ► “Earthquake, Magnitude”) is preferable.

Thus, for improving seismic hazard assessment, future studies must focus on combining in a systematic way E_S and M_0 determinations in order to fully harness the information provided by these two important physical parameters of the seismic source.

Earthquakes, Energy, Fig. 1 Upper panels: S - P time windows (see ► “Body Waves”) of the vertical component velocity seismograms recorded at station CCM for the 1991 Costa Rica (left) and the 1992 Nicaragua earthquake (right). Vertical broken lines mark the theoretical arrival times of the P and S phases. Middle panels: time-frequency analysis via the S -transform (Stockwell et al. 1996) calculated over the P -wave duration window (black record traces in the upper panels that are

also shown enlarged just above each middle panel); the color scales represent the amplitude of the S -transform in m/s. Lower panels: E_S and Me values as a function of time for different cumulative P -wave windows. The diamonds mark the end of the P -wave groups (see black record traces in the upper panels) that have been used for the single station E_S - Me estimates

Macroseismic intensity

Definition

The *intensity*, or *macroseismic intensity*, represents a classification of the severity of ground-motion shaking during an earthquake on the basis of observed effects at a given place (Grünthal et al. 1998). The word “macroseismic” refers to perceptible effects of earthquakes as opposed to instrumental observations.

Macroseismic Scales and Intensity Assignment

Earthquake intensities are defined in macroseismic scales. Since the early twentieth century, they usually contain 12 intensity degrees with the prominent exception of the seven degree Japanese Meteorological Agency (JMA) scale (later upgraded to ten degrees). Earthquakes generate different intensities at different places, generally decreasing with distance from the epicenter. The epicentral intensity can be used in combination with the hypocentral depth as a classification of earthquake strength – with restrictions for large earthquakes ($M \geq 7$) with extensive fault planes.

Although not a physical parameter as such, intensity is a measure of strength of shaking, which can be related to physical ground-shaking parameters. It is a shorthand

description of common observations from an earthquake, for example, instead of writing “the event was felt indoors by most, outdoors by few, and china and glasses clattered together,” one summarizes “intensity 5.”

Intensity data are capable of constraining the magnitude of an event with the same order of uncertainty as individual instrumental magnitude readings (Johnston 1996) and are essential in the study of historical earthquakes. Intensity data of an earthquake are usually presented in the form of a map showing for each intensity point either a corresponding color code or symbol. Contour lines in such maps separating intensities of different degrees are called *isoseismals*. The epicentral intensity is usually the largest observed intensity near to the epicenter or the barycenter of the highest intensity values. It can only be given for onshore events.

Intensity is an integer quantity. Uncertain intensity assignments can be expressed as, for example, 8–9 (meaning either 8 or 9), which may be used in numerical procedures as 8.5, without claim of precision. A macroseismic scale defines each intensity degree with a series of diagnostics. Each diagnostic describes typical effects of ground vibrations related to different sensors. For the lower intensities, the main sensors are people and objects indoors, whereas for higher intensities they are buildings, which suffer progressively more severe damage with increased intensities. The type of building, for example, masonry or reinforced concrete, its condition and workmanship, as well as the level of earthquake-resistant design influence its strength considerably.

Intensity values are often written using Roman numerals to emphasize the integer nature of intensity. However, as such numbers are hard to process in computer files, the practice is dying out.

The most recent scale in general use, the European Macroseismic Scale (EMS-98), fully considers the varying strength of buildings in the form of six vulnerability classes, five damage grades for both masonry and reinforced concrete structures, as well as differentiating structural and non-structural damage (Grünthal et al. 1998). Another element of the EMS-98 associated with the diagnostics is the relative frequency with quantitative definitions of the qualitative terms “few, many, most.” It is the only intensity scale supplemented by comprehensive guidelines and background materials, and this contributes, together with the other mentioned elements, to a reduction of the subjectivity, which often is associated with intensity assignments.

The EMS-98 is easily adaptable for use to the building stock anywhere in the world. Table 1 gives the short form of the EMS-98 as a very simplified and generalized description. The long, full version should be used for intensity assignments.

The EMS-98 should be the basis for intensity evaluation in European countries and has also been applied in a number of countries outside Europe. Some South European countries,

like Italy, still deploy Sieberg’s (1932) Mercalli-Cancani-Sieberg scale (MCS). The basic intensity scale used in North America is the Modified Mercalli scale (MMI). EMS-98 has also been applied in countries elsewhere. In China, the China seismic intensity scale (CSIS) has been used since 1999. This scale is related to the test version of the EMS-98, that is, the EMS-92 (Grünthal et al. 1993). While all these scales have 12 intensity degrees, the 1996 version of the JMA scale, introduced after the 1995 Great Hanshin earthquake, has been upgraded from originally seven degrees to ten degrees.

Nature of Sensors

Since intensity is a measure of earthquake shaking, it is important that scale diagnostics are effects that actually relate to shaking, such as the movement of objects and damage to buildings. Objects, buildings, and people make reliable sensors for deducing intensity; the natural environment does not provide good sensors. Especially, older intensity scales tend to include effects that may have been observed in an earthquake, but were not shaking related or not reliably associated with intensity degrees. Thus in Richter (1958; see below) intensity 11 is defined only by the bending of rail lines and damage to underground pipes. No amount of shaking will bend rail lines – such an effect is due to either fault rupture or ground failure. Ground failure and landslides are related to pre-existing slope vulnerability, which is unknown. Changes in well water level are influenced more by the condition of the water table than the actual strength of shaking (Vogt et al. 1994). Therefore, effects on natural surroundings as scale diagnostics are hard to use to advantage. This has the unfortunate result that it can be difficult if not impossible to assess intensity reliably away from settlements.

History of Intensity Scales

Historically, the use of intensities is important because it does not require instrumental measurements of earthquakes. In the last quarter of the nineteenth century, that is, before the establishment of instrumental seismology, macroseismic intensity became a widespread parameter. The first internationally introduced scale was the ten degree Rossi-Forrel scale of 1883, the use of which in some countries persisted up to the 1960s. This points to the relevance of knowing the different scales that have been used in different countries during different time periods. Here, only a short summary can be given. For a comprehensive compilation, see Musson et al. (2010) and Musson and Cčić (2002).

Earthquakes, Intensity, Table 1 Short form of the EMS-98

EMS intensity	Definition	Description of typical observed effects (abstracted)
I	Not felt	Not felt.
II	Scarcely felt	Felt only by very few individuals at rest in houses.
III	Weak	Felt indoors by a few people. People at rest feel a swaying or light trembling.
IV	Largely observed	Felt indoors by many people, outdoors by very few. A few people are awakened. Windows, doors, and dishes rattle.
V	Strong	Felt indoors by most, outdoors by few. Many sleeping people awake. A few are frightened. Buildings tremble throughout. Hanging objects swing considerably. Small objects are shifted. Doors and windows swing open or shut.
VI	Slightly damaging	Many people are frightened and run outdoors. Some objects fall. Many houses suffer slight nonstructural damage like hairline cracks and fall of small pieces of plaster.
VII	Damaging	Most people are frightened and run outdoors. Furniture is shifted and objects fall from shelves in large numbers. Many well-built ordinary buildings suffer moderate damage: Small cracks in walls, fall of plaster, parts of chimneys fall down; older buildings may show large cracks in walls and failure of fill-in walls.
VIII	Heavily damaging	Many people find it difficult to stand. Many houses have large cracks in walls. A few well-built ordinary buildings show serious failure of walls, while weak older structures may collapse.
IX	Destructive	General panic. Many weak constructions collapse. Even well-built ordinary buildings show very heavy damage: Serious failure of walls and partial structural failure.
X	Very destructive	Many ordinary well-built buildings collapse.
XI	Devastating	Most ordinary well-built buildings collapse; even some with good earthquake-resistant design are destroyed.
XII	Completely devastating	Almost all buildings are destroyed.

A later popular scale is Mercalli's version (with ten degree) from 1902. The first twelve degree scale is the one by Cancani (1904) with the focus on associating peak ground acceleration with single intensities. Based on the macroseismic observations from the 1911 $M_L = 6.1$ central European earthquake, Sieberg (1912) provided a completely revised twelve degree version with descriptions of the intensity degrees given in great detail. This scale, which overwhelmingly influenced all modern intensity scales, later became known as the Mercalli-Cancani-Sieberg (MSC) scale. Sieberg's (1923) minor revision of this scale was translated into English and published by Wood and Neumann (1931) in a largely condensed form, at the cost of clarity. The title is also inappropriate: the Modified Mercalli scale, MM-31. Sieberg's (1932) further revised version, with some major innovations, is still in use in parts of southern Europe as the MCS scale.

The MM-31 scale was completely overhauled in 1956 by Richter (1958). He refrained from associating his name with the new version to avoid confusion with the so-called Richter magnitude scale M_L , and he suggested it was to be known as the "Modified Mercalli scale of 1956" (MM-56).

Today's macroseismic evaluation procedures at the USGS rely basically on a version of the MM-31 scale by Stover and Coffman (1993) but in a newly edited and almost undocumented variant, that is, lacking differentiations in the terminology used, and in which extra rules and conventions are being applied (see Musson et al. 2010; Musson and Cčić 2002). Related intensity data sets are usually denoted only as MM or MMI.

In Europe, Medvedev, Sponheuer, and Kárník developed the MSK scale, introduced as MSK-64 (Medvedev et al.

1965a, b), on the basis of the MCS, the Russian GEOFIAN scale, and the MM-56. It is more systematically arranged than the forerunners and was widely adopted in Europe.

In 1988, the European Seismological Commission launched the updating of the MSK scale to bring it in line with modern earthquake-resistant building types and engineering requirements. After the new scale had been constructed, it was obvious that it contained so many new elements with respect to the MSK scale that it should bear a new name, and so the test version EMS-92 and the EMS-98 were established. The English original of the EMS-98 can be downloaded from <http://www.gfz-potsdam.de/EMS98> and also translations of the full scale into French, Italian, Spanish and Chinese. Translations of the core part and of the short form are also available in a total of altogether 30 languages. The availability in different languages is important since persons, not always fluent in English, act as observers and sensors in macroseismology.

An aspect connected with the history of intensity scales is the decline of interest in macroseismology in the middle of the twentieth century when instrumental monitoring was progressing. However, the late 1970s saw a revival of the subject since intensity assignments are fundamental for parametrizing historical seismicity and developing intensity-based ground-motion models essential in seismic hazard (see ► "Seismic Hazard") and risk assessments.

The design of the EMS-98 allows also its inverse use as risk predictive tool; i.e., the expected frequency of damage grades of buildings of different vulnerability classes can be assigned for a given intensity expected in a municipality for a certain occurrence probability (Musson 2000; Tyagunov et al. 2006).

Conversion of Intensity Scales

The conversion between intensity scales is, due to their integer nature, not possible in the way scalar parameters like different magnitude types can be converted. Ideally, conversions between intensities according to different scales should be avoided, and the original data should be reassessed using one scale. This is frequently not possible. Therefore, conversion diagrams have been developed in which the intensities according to different scales are represented as a series of “intensity ranges.” One scale, taken as a standard with equally large ranges, is, as it is perceived by different authors, compared with other scales with different ranges for the intensities. Musson et al. (2010) elaborate in more detail on this issue and present tables suggesting direct numerical correspondence. Among the twelve degree scales, Musson et al. (2010) conclude equality between EMS-98 and MCS, MMI, and MSK for the intensities 1–10. For intensities 11 and 12, the definitions in MCS, MSK, and MMI relate to phenomena, such as surface faulting, which do not represent strength of shaking or to a saturation of classification criteria in the scale where, for example, total damage refers to total damage to buildings without antiseismic design. Therefore, the intensities 11 and 12 do not have an equivalent in the EMS-98. The relation of the JMA-96 (JMA 1996) scale with the EMS-98 is given in Table 2.

Macroseismic Surveys

After an earthquake is felt, there are several ways to gather macroseismic data. The main source of data collection was in the past from questionnaires designed according to the diagnostics of the intensity-degree definitions. Questionnaires were especially used to compile data for the vast majority of observations in the range of intensities ≤ 6 , although many questionnaires were designed for diagnostics up to intensity 7 or 8.

Earthquakes, Intensity, Table 2 Conversion from the JMA-96 scale to the EMS-98. (After Musson et al. (2010))

JMA-96	EMS-98
0	1
1	2 or 3
2	4
3	4 or 5
4	5
5 Lower	6
5 Upper	7
6 Lower	8
6 Upper	9 or 10
7	11

Information on earthquake damage to buildings and other constructions need to be collected in the field. Special forms are in use in several high seismicity countries to optimize this procedure with respect to certain intensity scales and the building stock in a region.

Printed questionnaires used in the past have today been almost entirely replaced by Internet web-based versions. The “Did You Feel It?” (DYFI) program by the USGS (Wald et al. 1999a) is the basis of similar current activities worldwide. Musson (2006) describes the DYFI procedure for EMS-98 intensities in detail. The idea of such DYFI programs is that persons who have observed an earthquake use an Internet website to report the macroseismic effects through answering a multiple-choice questionnaire. Such DYFI programs are often not restricted to a certain country but can be applied internationally (see ► “Earthquakes, ShakeMap”).

The macroseismic data accumulated by the DYFI program represent a vast new source of engineering seismology data. The DYFI intensity data “make up in quantity what they may lack in quality. . . They are also robust and of surprisingly high utility” (Atkinson and Wald 2007).

Intensity Attenuation with Distance

The rate of decay of shaking strength with distance from the epicenter, that is, the intensity attenuation, is strongly dependent upon the focal depth h and to a lesser extent on the regionally dependent absorption of energy. Assuming a logarithmic proportionality between intensity and ground acceleration, an isotropic intensity-attenuation model results (Kövesligethy 1906), rewritten by Jánosi (1907) as

$$I_0 - I_i = 3 \log \left(\frac{r}{h} \right) + 3\alpha \log e(r - h) \tag{1}$$

with $r = \sqrt{R_i^2 + h^2}$, where R_i is the radius of the isoseismal intensity I_i , I_0 the epicentral intensity, α the absorption coefficient, and e is Euler’s constant. The same structure as Eq. (1) results in a logarithmic proportionality between intensity and seismic energy density (Howell and Schultz 1975; ► “Earthquakes, Energy”).

The first and, for a long time, the most important use of intensity attenuation was focused on depth determinations. For this purpose, graphical schemes by Sponheuer (1960) were frequently applied in the pre-computer era. In the case of good macroseismic data, the calculated depths coincide very well with instrumental depth determinations, at least for shallow (5–25 km) events with small source dimensions (Musson 1993). Intensity-attenuation relations of the type of Eq. (1) were determined from a few mean isoseismal radii. Only within the last two decades have modern statistical procedures been applied, which rely directly on a huge amount of

intensity data points. One of these relations based on Central European data after Stromeyer and Grünthal (2009) combined with Eq. (3) reads

$$I = 1.5M_w - 0.45 \log(h) + 0.15 - 2.95 \log\left(\frac{r}{h}\right) - 0.0025(r - h) \quad (2)$$

where I is the intensity at epicentral distance r . Gomez Capera (2006) compiled several intensity-attenuation relations of this type.

Well-established models of intensity attenuation with distance are especially required for operating ShakeMap programs, i.e., rapid post-earthquake information systems (see ► “Earthquakes, ShakeMap”), for earthquake early warning systems (see ► “Earthquakes, Early and Strong Motion Warning”), and for other quantitative scientific studies like intensity-based seismic hazard and risk assessments.

Conversion of Intensities to Magnitudes

Intensity data give surprisingly robust measures of earthquake magnitudes (see ► “Earthquake, Magnitude”). This important fact qualifies the macroseismic method to be used for magnitude determinations of historical earthquakes occurring in early or pre-instrumental times. Seismic hazard analysis greatly benefits from long-term earthquake catalogues. There are three ways of macroseismic magnitude determinations based on the following: (1) the epicentral intensity, (2) the areas affected by certain intensity levels, and (3) the entire field of intensity data points. These ways are described below.

1. A few years after the introduction of the earthquake magnitude, the first empirical relation with the epicentral intensity I_0 was given (Gutenberg and Richter 1942, 1956). The maximum or epicentral intensity is in many cases the only information at hand for historical earthquakes. I_0 is strongly affected by the focal depth h . Therefore, h should be taken into consideration, or the seismogenic depth in an area should be narrowly constrained at the conversion to magnitude. A relation based on well-constrained moment magnitude M_w , I_0 , and h of European earthquakes given by Grünthal et al. (2009) reads.

$$M_w = 0.667 I_0 + 0.30 \log(h) - 0.10 \quad (3)$$

or omitting h

$$M_w = 0.682 I_0 + 0.16 \quad (4)$$

These relations are valid for the ranges $5 < I_0 < 9$, $3.0 < M_w < 6.4$, $5 \leq h[\text{km}] < 22$.

2. For earthquakes with known total felt area or known area enclosed by one or more of the n (preferably) outer isoseismals (An), the magnitude can be determined as a function of $\log An$. Johnston (1996) derived regression relations for MMI isoseismal areas for stable continental regions to predict seismic moments M_0 according to a functional regression form proposed by Frankel (1994).

$$\log M_0 = a + b \log An + c\sqrt{An} \quad (5)$$

From the published relations for different isoseismal areas, the coefficients for the areas of intensity 3 and 4 read

	a	b	c
A3	17.59	1.020	0.00139
A4	18.10	0.971	0.00194

The uncertainties in the derived moment magnitudes can be halved by applying weighted averaging of a suite of isoseismal areas. The uncertainties are then in the range of $\pm 0.15 \dots 0.23 M_w$ units.

3. The most advanced methods to derive magnitude from macroseismic data use the intensity data points of an event to make a joint determination of epicenter location (see ► “Earthquakes, Location Techniques”) and magnitude. These methods need a well-calibrated intensity-attenuation model valid for a certain region. The most important methods of this type are by Bakun and Wentworth (1997), originally developed for Californian earthquakes $4.4 < M_w < 6.9$ and by Gasperini et al. (1999) for Italian earthquakes with $M_S \geq 5.5$. The latter additionally provides the fault azimuth, essentially derived from the direction of maximum elongation of the highest intensity data points.

Relation of Intensities to Recorded Strong Ground Motion

Attempts to express the strength of an earthquake and its observed effects in the form of physical parameters date back to the last quarter of the nineteenth century (cf. summary in Grünthal 1984). Omori (1900) and Cancani (1904) were the first who related intensity degrees to peak ground acceleration (PGA) (see ► “Earthquakes, Strong-Ground Motion”). Kövesligethy (1906) and Jánosi (1907) invented a functional form that is still used today – a linear regression between intensity I and the logarithm of Cancani’s PGA ($I = a + b \log(PGA)$). Grünthal (1984) compiled 30 published relations of intensity to peak ground motion, which showed a larger scatter in PGA compared to peak ground velocity (PGV).

For the implementation of the USGS ShakeMap software package (see ► “Earthquakes, ShakeMap”; Wald et al. 1999b),

Earthquakes, Intensity, Fig. 1 Relations between intensity versus PGA (left) and PGV (right) after Wald et al. (1999c), Faccioli and Cauzzi (2006), and Faenza and Michelini (2010). Although MMI values and

MCS values are used in these studies, the relations are given in a common scheme according to their de facto equivalence (Musson et al. 2010). (Redrawn after Faenza and Michelini (2010))

representing shaking through maps of PGA, PGV, and ground-motion shaking intensity, it was necessary to derive “instrumental intensity” by converting peak ground motion to MMI intensity values (Wald et al. 1999c; Fig. 1). In Europe, notably Italy, well-established relations for MCS intensities have been developed by Faenza and Michelini (2010) and references therein. Their orthogonal relations (Fig. 1) read

$$I = 1.68 + 2.58 \log PGA \text{ [cm/s}^2\text{]} \quad (6)$$

$$I = 5.11 + 2.35 \log PGV \text{ [cm/s]} \quad (7)$$

The densest network to generate ShakeMaps in terms of instrumental intensity exists in Japan. Here, the instrumental intensity according to the JMA scale (I_{JMA}) is computed from Fourier acceleration spectra multiplied with different filter functions (Kuwata and Takada 2002; Karim and Yamazaki 2002). Empirical relationships between I_{JMA} and different ground-motion parameters are given by Karim and Yamazaki (2002). Their relation between I_{JMA} and PGA was derived as

$$I_{JMA} = 1.58 + 1.38 \log SI + 0.59 \log PGA + 0.02 M \quad (8)$$

where SI is the “spectrum intensity” (cm/s^2) introduced by Housner (1961) as the integral over the velocity response spectrum in the period range from 0.1 to 2.5 s, and PGA is in cm/s^2 . However, correspondence between “instrumental intensity” and the wording of the macroseismic scale cannot be taken for granted.

The limitation of all these relationships is that intensity is not a function of either PGA or PGV, contrary to the

assumption firstly made by Omori (1900) and Cancani (1904), and the correlation is purely an indirect one. The duration of strong shaking is critical in determining earthquake damage (see, for instance, Gibson et al. 1995), and hence equations of the form of (6), (7), and (8) always have enormous scatter.

Conclusions

Macroseismic intensity is a robust measure of perceptible and potentially damaging ground motion and is essential in engineering seismology. Modern developments of macroseismic scales, defining intensity degrees with persons and buildings as sensors, fully consider the range of vulnerability of buildings and differentiate structural and nonstructural damage patterns. Intensity provides the principal means by which one can parameterize historical or pre-instrumental earthquakes, that is, to determine their location, magnitude, and focal depth. Good quality macroseismic data enables a similar range of uncertainty in the derived focal parameters as standard instrumental seismology. The increased relevance of the parameter macroseismic intensity is strongly related to the enhanced needs in reliable seismic hazard and risk assessments. With the Internet-based platforms ShakeMap and “Did You Feel It?”, macroseismic intensity has become omnipresent.

Stable continental earthquakes

Definition

The plate tectonics revolution of the mid-twentieth century provided Earth scientists with the fundamental framework to understand why most earthquakes occur within geographically limited active belts around the world along the plate boundaries. However, large devastating continental earthquakes do also occur in the plate interior far away from plate boundaries, which are known as intraplate earthquakes.

Mechanism of Intraplate Earthquakes

Moderate to large size devastating continental intraplate earthquakes have occurred at many locations in the world, e.g., 1811–1812 New Madrid (USA); 2008 Wenchuan (China); 2016 Christchurch (New Zealand); 1988 Tennant Creek (Australia); 1989 Ungava (Canada) and 2001 Kachchh, Koyana; and 1993 Latur, India. The occurrences of these earthquakes account for only 0.5% of the average annual global energy release by earthquakes (Johnston and Kanter 1990). The locations and mechanisms of $M \geq 6$ intraplate earthquakes during 1900–2019 are listed in Table 1, with 46% thrust, 46% strike-slip, and 8% normal mechanisms. Thus, in general, these earthquakes occur in compressive stress regime. Nevertheless, these earthquakes are rare and can occur near to the thickly populated areas, causing large number of deaths/injuries as well as financial losses. The

recent occurrences of continental earthquakes have caused substantial damages and deaths due to the growing population and poor constructions. The 2001 Bhuj (India) of $M_w 7.7$ had claimed ~20,000 human lives, while the most devastating 2008 Wenchuan (China) earthquake of $M_w 7.9$ claimed ~87,000 human lives.

The generation of intraplate earthquakes has been attributed to the sudden movement along the pre-existing weak zones due to local stress perturbation related to the regional plate boundary forces, topography and crustal density inhomogeneities, reservoir loading, presence of fluids, etc. (Campbell 1978; Mareschal and Kuang 1986; Johnston and Kanter 1990). There are numerous examples of intraplate earthquake nucleation at the intersections of weak zones or along old rifts in response to the regional plate boundary forces (Talwani and Rajendran 1991; Johnston and Kanter 1990). In 1978, Campbell proposed that crustal intrusive bodies may also induce significant localized stresses in a stable continental setup. However, the intermediate to deep crustal earthquakes of moderate-to-large magnitudes have occurred in several continental rift zones like the Amazon (Brazil), East Africa (Africa), Baikal (Russia), Rio Grande (USA), Kachchh (India), Narmada (India), and Reelfoot (New Madrid, USA), which have been explained in terms of failure of old rift due to local stress perturbations associated with substantial crustal as well as asthenospheric thinning, intruded magmatic material from the underlying mantle and deepening of the brittle-ductile transition depth (Nyblade and Langston 1995; Johnston and Kanter 1990; Pollitz et al. 2002). Various local stress sources have been explored so far to explain the seismicity associated with the New Madrid (USA) and Kachchh (India) rift zones (Johnston 1996; Mandal 2019). For instance, New Madrid seismicity has been attributed to stress changes induced by melting of the Laurentide ice sheet or stresses generated by sinking of an ancient high-density mafic body or from a sudden weakening of the lower crust (Pollitz et al. 2002). Similarly, the seismicity in Kachchh (India) has been attributed to the stresses caused by mafic crustal intrusive bodies and in-plane plate compression, which has further been facilitated by the presence of aqueous fluids or volatile CO_2 released from the metamorphism of olivine-rich lower crustal rocks (Mandal 2019).

In typical continental rift zones, like New Madrid (USA) and Amazon (Brazil), the intraplate earthquake occurrences are attributed to localized stress generation due to density heterogeneity in the deep lower crust (Zoback and Richardson 1996). It is observed that the local tectonic forces, such as topography, and crustal density heterogeneities can contribute a sizable amount of differential stresses of the order of 100 MPa to the lithospheric stress regime (Mareschal and Kuang 1986). These stresses were also well correlated with

NO: Normal

NS: normal with strike-slip component

SS: Strike-slip

ST: strike-slip with thrust component

SN: strike-slip with normal component

the geographical distribution of intraplate earthquakes in some regions of the USA, Canada, and India (Mareschal and Kuang 1986; Mandal et al. 1997). A good agreement between the occurrences of intraplate earthquakes with the change in lithospheric elastic thickness owing to rheology and local buoyancy forces has been noticed in the Western USA that shows the importance of local tectonic forces over the plate tectonic forces in causing intraplate seismic activity (Lowry and Smith 1995).

Summary and Conclusions

Intraplate earthquake generally occurs in the strong continental crust; thus, their seismogenesis is not well understood. Multidisciplinary geophysical and geological studies are required to understand their causative mechanism. In general, it is observed that large intraplate earthquakes can cause significant devastation to mankind; thus, the hazards concerning the occurrences of these earthquakes are very

important to access for taking proper preventive measures to create an earthquake-resilient society.

Hypocenter determination

Definition

Earthquake location. Methods for determining the latitude, longitude, depth, and time of origin of a seismic event (earthquake, explosion, etc.) using the arrival times of seismic waves.

Introduction

Knowing the location of an earthquake (its latitude, longitude, depth, and origin time) is an essential starting point for the vast majority of quantitative seismological analyses. In the context of this entry, earthquake location will be taken to mean determining the initiation point of fault rupture, i.e., the hypocenter. After briefly tracing some of the early history of methods for the quantitative determination of earthquake locations, the focus of discussion turns to modern methods for single-event location and uncertainty estimation. The final section covers multiple-event location, with an emphasis on the substantial to – in some cases – profound improvement in relative location accuracy that can be achieved by combining waveform cross-correlation with relative location techniques.

Early History

John “Earthquake” Milne devised some of the first quantitatively based methods for earthquake location, known as the methods of circles, hyperbolas, and coordinates (Milne 1886). For the method of circles, the difference in arrival time between later observing stations i ($i = 1, N$) and the first observing station 0, $t_i - t_0 = dt_i$, is used to construct circles of radii $V dt_i$, where V is the velocity of “shock” (i.e., seismic wave) propagation, and the center of the circle through station 0 that is roughly tangent to all the other circles defines the earthquake epicenter. The scale factor V is determined by trial and error. The commonly taught S minus P time location method (Bolt 2006) is similar in concept. The method of hyperbolas is a variant on the method of circles, whereby differential times between pairs of stations are used to define hyperbolas of possible locations and the intersection of hyperbolas defines the earthquake epicenter. The method of coordinates goes a step further by setting up a system of four equations (defined in Cartesian coordinates centered on the last observing station) relating differential times to “shock” velocity and the (x,y,z) coordinates of the earthquake. With four equations and four unknowns, the solution is unique. These methods were employed for many years, until slowly the method of Geiger (1910, 1912), discussed below, began to supplant it. Interestingly, Milne’s methods have been revived recently for use in locating earthquakes in an early warning system (Satriano et al. 2008) and in tectonic (Zhou 1994; Font et al. 2004) and volcanic (Sumiejski et al. 2009) settings.

Single-Event Location

The predominant method for earthquake location is based on what is commonly known as Geiger’s method, which was developed early in the twentieth century (Geiger 1910, 1912). This method involves deriving the least-squares (L2 norm)

solution to a set of equations, for a trial hypocenter, of the form

$$r_i = \sum_{j=1}^3 \frac{\partial T_i}{\partial x_j} \Delta x_j + \Delta t_0 \quad (1)$$

where r_i is the residual at station i , defined as the observed arrival time of a seismic phase t_i minus the calculated arrival time given by the origin time t_0 plus the calculated travel time T_i , the x_j 's are the hypocenter coordinates, and Δ indicates the (unknown) parameter perturbations. The spatial derivatives $\partial T_i / \partial x_j$ have a simple relationship to the seismic velocity V and the ray direction at the source,

$$\frac{\partial T_i}{\partial x_j} = \frac{-1}{V} \frac{dx_j}{ds} \quad (2)$$

where s is the path length parameter. Equation 1 represents a nonlinear parameter estimation problem (Aster et al. 2019), so it is solved iteratively, and some convergence criteria must be defined. Mathematically, this problem can be expressed as

$$\mathbf{G}\Delta\mathbf{m} = \mathbf{r} \quad (3)$$

where the matrix $\mathbf{G}$ contains the partial derivatives, $\Delta\mathbf{m}$ is the vector of hypocenter perturbations (position and origin time), and $\mathbf{r}$ is the residual vector. Equation 3 is typically solved using iterative least squares, generally with some type of regularization (Aster et al. 2019). For a layered model, Geiger's method can be extended from this simple linearized form to a nonlinear form (Thurber 1985), but that is of more theoretical than practical interest.

The seismic phases used for location vary depending in part on the epicentral distance domain – local (0° to 5°), regional (5° to 30°), and teleseismic ($>30^\circ$) (note that these breakpoints are relatively standard ones, although that for the local-regional is somewhat more arbitrary). At local distances, first-arriving P and S phases are used almost to exclusion. At teleseismic distances, first-P and to a lesser degree first-S remain critically important, albeit with such complications as shadow zones and triplications, but a virtual cornucopia of other phases is also available. Among them, the depth phases (solid-surface reflections pP and sP and the water-surface reflections pwP and swP), which have travel-time derivatives for depth opposite in sign to the direct phases, have tremendous value in constraining event depth, although misidentification problems can be significant (Engdahl et al. 1998; 2006). The outer core reflection PcP has also proven quite useful (Schöffel and Das 1999).

At regional distances, several factors combine to make the location situation complex. The mantle refractions Pn and Sn are the first-arriving body-wave phases, and their amplitudes

can be small relative to crustal arrivals. Crustal thickness variations at a regional scale make accurate prediction of regional travel times difficult. These problems have an enormous impact on nuclear explosion monitoring efforts, where the goal is to be able to locate relatively small events often with only sparse regional data. The use of later-arriving phases (crustal body-wave phases Pg, Sg, and PmP, and the surface-wave phase Lg) and also arrival azimuth is relatively common for this monitoring domain (Bratt and Bache 1988). Arrival azimuth can be determined at high precision with a seismic array or by a single three-component station with much lower precision.

There are some alternatives to Geiger's method, most of which fall into the general category of nonlinear optimization (Gill et al. 1981). One is the conceptually simple grid search approach (Rowlett and Forsyth 1984; Sambridge and Kennett 1986; Shearer 1997; Lomax et al. 2000; Rodi 2006). Others include the simplex method (Rabinowitz 1988), genetic algorithms (Sambridge and Gallagher 1993), and simulated annealing (Billings et al. 1994). Because these methods do not involve least squares and the calculation of derivatives (Eqs. 2 and 3), they are readily amenable to the use of the more robust L1 norm (Aster et al. 2019), and some can directly provide comprehensive uncertainty information, a topic we turn to next.

Location Uncertainty

In some circumstances, knowing the uncertainty of a seismic event's location may be nearly as important as the location itself. The discussion of this topic can be separated into two parts, precision and accuracy. Precision is covered first, including a brief discussion of arrival-time estimation (phase picking). Accuracy is a far more subtle issue, with significant limitations on our ability to assess it thoroughly. Husen and Hardebeck (2010) discuss these topics in detail.

The standard approach for the evaluation of precision is the confidence ellipsoid (Flinn 1965), which can be obtained from the model covariance matrix (Aster et al. 2019) for Eq. 3,

$$\mathbf{C}_m = \sigma_d^2 (\mathbf{G}^T \mathbf{G})^{-1} \left[(\mathbf{G}^T \mathbf{G})^{-1} \right]^T \quad (4)$$

where for now we assume that the data errors have a uniform standard deviation σ_d , often estimated from the data misfit, and are uncorrelated (independent). Given the desired confidence level p (e.g., 0.95), the corresponding confidence ellipsoid is obtained for $\mathbf{m}$ satisfying

$$(\mathbf{m} - \mathbf{m}^*)^T \mathbf{C}_m^{-1} (\mathbf{m} - \mathbf{m}^*) = \kappa_p^2 \quad (5)$$

where $\mathbf{m}^*$ is the location solution and κ_p^2 is given by

$$\kappa_p^2 = 4\sigma_d^2 [F_p(4, N-4)] / (N-4) \quad (6)$$

with F_p the F statistic at confidence level p and N the number of arrival-time data (Draper and Smith 1981). Some limitations of this approach to uncertainty estimation are (1) that the misfit-based estimate of σ_d becomes unreliable for small numbers of observations (Evernden 1969), (2) that it neglects the effects of velocity model inaccuracy and correlated errors, and (3) that the linear approximation itself is inadequate in some circumstances.

Buland (1976) noted that data uncertainty estimated from either the misfit or a priori experience is generally too small due to the inaccuracy of the travel-time model. He suggested that the σ_d value should simply be increased to compensate for this problem. Jordan and Sverdrup (1981) developed an elegant statistical approach for making this compensation. Their philosophy is to replace the usual a posteriori estimate of the data variance, s_d^2 , based on the data misfit for an individual earthquake,

$$s_d^2 = \|\mathbf{r}\|^2 / (N-4) \quad (7)$$

with an estimate based on a combination of a priori and a posteriori information:

$$s_d^2 = \frac{K s_0^2 + \|\mathbf{r}\|^2}{(K + N - 4)} \quad (8)$$

where the a priori variance estimate s_0 is given a relative weight of K . Thus the a priori information is treated as contributing K observations to the estimate of s_d^2 and the data for the particular event contribute N observations. For self-consistency, given a large number of events, the mean of the estimated variances should approach s_0 . Jordan and Sverdrup (1981) also show that the distribution of the estimated standard deviation needs to be consistent with the adopted value of K . In the limit of no prior information ($K = 0$), their estimate reverts to the standard formula (Flinn 1965), whereas for infinite prior information ($K = \infty$), their estimate becomes equivalent to that of Evernden (1969).

One limitation of the Jordan and Sverdrup (1981) approach is that it assumes an uncorrelated, Gaussian error distribution with a constant data variance for all observations. Varying data uncertainty estimates can be incorporated simply by including a weighting matrix $\mathbf{W}$ in the standard linearized analysis (Aster et al. 2019):

$$\mathbf{W} \mathbf{G} \Delta \mathbf{m} = \mathbf{W} \mathbf{r} \quad (9)$$

(e.g., Bolt 1960) and then solving the weighted system as before. Weighting is generally done based on reported arrival-time reading precision (Engdahl et al. 1998), reported arrival quality (Buland 1976), phase variance as a function of

distance (Engdahl 2006), residual size (Bolt 1960), station distance (Klein 1978), and/or azimuthal distribution of stations (Buland 1976). However, the Gaussian data error assumption is generally inappropriate, as residual outliers are common in arrival-time data (Bolt 1960; Buland 1986). Discussions of correlated errors and their treatment can be found in Chang et al. (1983), Rodi and Myers (2007), and Bondár and McLaughlin (2009).

The “uniform reduction” method (Jeffreys 1939) is effective for treating the situation of normally distributed errors plus a background of outliers. Bolt (1960) assumed a residual frequency distribution of the form

$$f(r) = a s + \frac{(1 \pm s)}{\sigma \sqrt{2\pi}} \exp \left(\pm \frac{(r \pm m)^2}{2\sigma^2} \right) \quad (10)$$

where a and s are constants and m and σ are the mean residual and its standard deviation. This corresponds to a residual weighting function of the form

$$w(r) = \left[1 + \mu \exp \left(\pm \frac{(r \pm m)^2}{2\sigma^2} \right) \right]^{\pm 1} \quad (11)$$

with $\mu = \sigma (2\pi)^{1/2} a s / (1 - s)$.

It is important to point out that estimating phase arrival times by itself is a difficult problem, particularly for S waves and other secondary phases. Many seismic networks use automated pickers, at least for preliminary locations. Simple auto pickers use a threshold of the ratio of the short-term average (STA) to the long-term average (LTA) of the signal amplitude (Allen 1978, 1982; Ruud and Husebye 1992). There are a wide variety of other (generally more computationally demanding) approaches. Among these are energy analysis (Earle and Shearer 1994), polarization analysis (Vidale 1986; Cichowicz 1993), autoregressive techniques (Maeda 1985; Sleeman and Eck 1999; Leonard and Kennett 1999; Leonard 2000), wavelet analysis (Zhang et al. 2003), or some combination (Wang and Teng 1997; Diehl et al. 2009).

As noted above, constraints on event locations can be improved markedly via the inclusion of secondary arrivals. Gomberg et al. (1990) and Wilcock and Toomey (1991) examine the importance of even a single S arrival in reducing location uncertainty. A “chicken and egg” problem with the use of later phases is that their correct identification often requires knowledge of the event depth and distance. Recognizing this problem, Kennett et al. (1995) and Engdahl et al. (1998) included a phase reassociation step in their location procedure. In their approach, catalog phase arrivals were reidentified after each relocation iteration using a statistically based association algorithm. This approach can be implemented by comparing probability density functions (PDF’s) for relevant phases, centered on their theoretical relative travel times for a given hypocenter, to the observed phase arrivals. When PDF’s overlap for a particular

phase, the idea is to assign a phase identification in a probabilistic manner based on the relevant PDF values, making sure not to assign the same phase to two different arrivals.

The above discussion focuses almost exclusively on location precision. There are two general approaches for evaluating location accuracy: theoretical and empirical. Pavlis (1986) carried out a thorough theoretical analysis of both precision and accuracy aspects for local earthquakes. He identified and evaluated three sources of hypocenter error: (1) measurement errors, (2) velocity model errors, and (3) nonlinearity. He treated the first via standard confidence ellipsoids, but the other two required the establishment of error bound estimates. Billings et al. (1994) explored aspects of (1) and (2) for the teleseismic case using a combination of Monte Carlo analysis and varying sets of observations, although their analyses involved real data, not synthetic data. One general conclusion of both these studies is that velocity-model-induced errors can be as significant as measurement errors.

“Ground truth” (GT) events provide a direct, empirical means to explore absolute location accuracy (also termed location bias). Having GT events allows one to evaluate location and uncertainty estimation strategies empirically that, for example, produce 95% confidence ellipses that overlap the true locations 95% of the time. This avenue of research has been motivated primarily by nuclear explosion monitoring needs (see ► “[Seismic Monitoring of Nuclear Explosions](#)”) but also is an important aspect of research on one-dimensional (1D) and three-dimensional (3D) earth models (see ► “[Seismic Tomography](#)”). See Bondár and McLaughlin (2009) and references therein for recent work on absolute location accuracy and Thurber and Engdahl (2000) for a review of the development of global 1D models.

The San Andreas Fault Observatory at Depth (SAFOD) provided a unique test of absolute location accuracy. One of SAFOD’s goals (unfortunately not yet realized) was to penetrate the rupture zone of a magnitude ~2 repeating earthquake. This required determining a borehole trajectory that would pass within 100 m of the target event. Using data from a dense temporary array, permanent networks, deep borehole instruments, and active-source experiments, Thurber et al. (2004) carried out 3D tomography and used “virtual earthquakes” (receiver gathers of shots recorded on borehole instruments, effectively providing sources of known location at depth) to assess absolute location accuracy. Their work succeeded, as subsequent borehole recordings of target earthquake aftershocks showed the target event to lie within 100 m of the borehole (Zoback et al. 2011).

Multiple-Event Location

There are two distinct but complementary aspects to this topic that will be discussed. One is the suite of methods used to

infer the relative locations of events, including joint hypocenter determination (JHD), hypocentroidal decomposition (HDC), and double-difference (DD) methods. Note that local earthquake tomography takes multiple-event location a step further to determine seismic velocity structure simultaneously with the locations of many earthquakes (see ► “[Seismic Tomography](#)”). The other is the use of waveform cross-correlation (WCC) methods to determine differential times (DT’s) and/or pick adjustments.

The use of catalog DT’s for determining relative locations of earthquakes (or explosions) has been a fruitful field of work for many decades (e.g., Douglas 1967). The precision of WCC DT’s allows for spectacular relative location results to be achieved over a broad range of spatial scales when DT’s from WCC are used in combination with joint location techniques. These and other studies have demonstrated the substantial improvement in the delineation of seismogenic features or in the accuracy of relative locations of GT events that is possible using multiple-event location methods in concert with high-precision arrival-time or differential-time data. WCC is covered first to streamline the subsequent discussion of the relative location techniques.

Waveform Cross-Correlation

For a pair of earthquakes that are located close to each other (relative to the predominant wavelength of the seismic signal from them) and have similar source mechanisms, the waveforms from them observed at a particular seismic station will be similar. The work by Poupinet et al. (1984) to use (frequency domain) WCC on the coda of similar earthquakes (“doublets”) to detect temporal changes in seismic velocity followed by the study of Fremont and Malone (1987) using the same WCC method to determine high-precision relative arrival times and earthquake locations at Mt. St. Helens ultimately led to an explosion in the use of WCC and location techniques in the 1990s and beyond.

The time-domain method for WCC is relatively simple although computationally demanding for large sets of events. Windowed waveform segments spanning the time of the relevant arrival (P or S) for a pair of earthquakes at a particular station are cross-correlated over a range of lag times to find the time lag corresponding to the best alignment of the waveforms (i.e., the maximum CC value). Waveforms are typically filtered either with a simple bandpass filter or with coherency weighting (Rowe et al. 2002a). For very similar events (those with a high CC value), it can be worthwhile to apply a frequency-domain technique such as cross-spectral phase to determine the lag to a precision below the sample rate. This procedure takes advantage of the fact that, as an example, for two frequencies that are a factor of two different, the phase difference at the higher frequency should be exactly double that at the lower frequency. The lag is determined by calculating the phase difference as a function of frequency and

fitting the result with a straight line through the origin at zero frequency.

Most of the studies using WCC adopt a threshold value (typically 0.7) below which DT's are discarded. This can result in good data being lost (correct lag value but low CC value – e.g., due to a noisy record) as well as bad data being used (incorrect lag value but high CC value – e.g., due to a cycle slip). Du et al. (2004a) developed a procedure to provide independent lag estimates for verification of WCC results. They used the bispectrum (BS) method, which works in the third-order spectral domain, to check the reliability of the CC-determined time delay. They calculated two time delays with the BS method, one using the bandpass-filtered waveforms and the other with the raw data, and used them to verify (select or reject) the CC estimate computed with the filtered waveforms. This approach appears to be particularly effective in reducing cycle-slip errors.

Relative Location

As noted above, the JHD method dates back to the work of Douglas (1967). In its basic form, the method takes the basic equation for earthquake location, Eq. 1, adds a “station correction” term Δs_i , and sets up a large set of equations for a suite of events, $k = 1, K$:

$$r_{ik} = \sum_{j=1}^3 \frac{\partial T_{ik}}{\partial x_{jk}} \Delta x_{jk} + \Delta t_{ok} + \Delta s_i \quad (12)$$

As noted by Wolfe (2002), JHD procedures assume that if the hypocentral separations among a set of earthquakes are small compared to the event-station distance and the scale length of heterogeneity, then the ray paths between the source region and a station are similar, and the travel-time error introduced by an incorrect velocity model has a nearly constant value for a given station, thus justifying the linear term Δs_i . Pujol (2000) provides a review of JHD methods mostly aimed at local-scale studies. Pavlis (1992) presents a comprehensive analysis of relative location errors.

Wolfe (2002) thoroughly analyzed the HDC and DD methods. Her analysis shows that the solutions for both operators are similar, with the double-difference operator weighting fits to travel times on stations that record more earthquakes more heavily. The HDC method was introduced by Jordan and Sverdrup (1981). As the name indicates, it involves decomposing the system Eq. 12 via projection operators into one involving just the locations of the events relative to the (unknown) average location (i.e., the hypocentroid). As Wolfe (2002) notes, the projection is in fact a travel-time differencing operation. The DD method of Waldhauser et al. (1999) and Waldhauser and Ellsworth (2000) constructs the event-pair difference equations directly, but it is distinguished from the original Jordan and Sverdrup

(1981) method by evaluating the spatial derivatives at different points rather than assuming they are constant and by including a separation-dependent weighting in order to reduce location-dependent path bias. Modern HDC methods also allow for spatially varying derivatives (Bergman and Engdahl 2001), and the appropriateness of separation-dependent weighting has been subject to debate. The Markov Chain Monte Carlo approach of Myers et al. (2007) takes a probabilistic approach that incorporates the probability of phase identification errors in the estimation of uncertainty.

Some examples of applications of WCC combined with relative location for microearthquakes at a local scale include Switzerland (Deichmann and Garcia-Fernandez 1992), Kilauea volcano, Hawaii (Got et al. 1994; Rubin et al. 1998), California (Dodge et al. 1995; Shearer 1997; Waldhauser et al. 1999; Waldhauser and Ellsworth 2000; Schaff et al. 2002), Iceland (Slunga et al. 1995), the Soultz geothermal field, France (Rowe et al. 2002b), Mount Pinatubo, the Philippines (Battaglia et al. 2004), New Zealand (Du et al. 2004b), and Soufriere Hills volcano, Montserrat (Rowe et al. 2004). At a regional scale, Schaff and Richards (2004) determined relative locations for an earthquake sequence in China using WCC on Lg waves. For teleseismic data, WCC/relative location methods have been applied to body waves for nuclear explosions at the Balapan test site (Phillips et al. 2001; Thurber et al. 2001), to the aftershock sequences of the great Sumatra earthquakes (Pesicek et al. 2010), and to global seismicity (Waldhauser and Schaff 2008).

Time Reversal and Migration Location

An idea adapted from the exploration industry by McMechan (1982), but long-established in the acoustics literature (Andersen et al. 2008), completely avoids arrival-time picking, instead relying on the time reversibility of the wave equation to “image” earthquake source locations. In a classic (but “reciprocal”) time-reversal experiment reported by Parvulescu and Clay (1965), a microphone was placed about 25 ft away from a loudspeaker in a room, and short impulsive signals were emitted by the loudspeaker and recorded on tape through the microphone. The tape was then played back in reverse through the loudspeaker, resulting in a simple “click” sound at the microphone due to the reverse-time focusing of the signal. A similar field demonstration was successfully carried out with two research ships at an oceanic trench (Parvulescu and Clay 1965). See the encyclopedia entry on time reversal in seismology by Larmat and Clay (2019). Time-reversal localization of microearthquakes in near-real time is now common practice in the enhanced petroleum recovery (fracking) domain, where it is generally termed migration location (Artman et al. 2010). An

accurate seismic velocity model is important for effective focusing at the hypocenter, and the quality of the results is dependent on the acquisition geometry, as well as signal-to-noise ratio. Pesicek et al. (2014) compared pick-based, double-difference location with cross-correlation to migration for an industry dataset. The two methods yielded comparable results, but the migration approach may be preferred for small aperture surface arrays due to its rapid processing capability.

Summary

Despite being one of the oldest quantitative problems in seismology, it is clear that there is still much to learn about earthquake location. The combination of WCC and high-precision relative location brought new excitement to this rather old field of research, and time-reversal methods are providing an approach that is very effective in near-real-time analysis situations. At the same time, the needs of nuclear explosion monitoring have motivated the careful study of absolute location capability and statistically consistent uncertainty estimation.

Earthquakes, PAGER

David J. Wald, Kishor S. Jaiswal, Kristin D. Marano and Michael Hearne
U.S. Geological Survey, Denver Federal Center, Lakewood, CO, USA

Definition and Introduction

PAGER, short for Prompt Assessment of Global Earthquakes for Response, is an automated system developed and run by the US Geological Survey (USGS) that produces information concerning the impact of significant earthquakes around the world within approximately 20 min of any magnitude 5.5 or larger event. PAGER rapidly assesses earthquake impacts by combining populations exposed to estimates of shaking intensity with models of economic and fatality losses based on past earthquakes in each country or region of the world. The main purpose of the PAGER system is to inform emergency responders, government and aid agencies, and the media regarding the scope of the potential disaster. Earthquake alerts – which were formerly sent based on event magnitude and location or population exposure to shaking – are generated based on the estimated range of fatalities and/or economic losses.

The USGS's National Earthquake Information Center (NEIC) in Golden, Colorado, locates over 30,000 earthquakes a year. Tragically, about 20–30 of these cause significant damage, injuries, or fatalities. The USGS often detects earthquakes well before eyewitness reports are available. The USGS must then decide rapidly whether Federal and international agencies should be alerted to a potentially damaging event. In the past, the USGS primarily relied on the experience and intuition of its on-duty seismologists to estimate the impact of an event. To quantify and improve the accuracy of

the assessment, the USGS has developed PAGER, an automated system to rapidly estimate the shaking distribution, the number of people and settlements exposed to severe shaking, and the range of possible fatalities and economic losses. The estimated losses in turn trigger the appropriate color-coded alert (green, yellow, orange, or red), which correspond to suggested levels of response: no response, local/regional, national, or international response, respectively. In addition to direct alert notifications, PAGER provides important supplementary information, including comments describing the dominant types of vulnerable buildings in the region, population exposure, fatality reports from a few previous nearby earthquakes, and a summary of regionally specific information concerning the potential for secondary hazards, such as earthquake-induced landslides, tsunamis, and liquefaction. A map provides quick visual overviews of shaking levels and population densities, and a table summarizes the predicted shaking intensity at nearby cities and towns. This impact summary information is available on an event-by-event basis on the USGS Earthquake Program web site [<http://earthquake.usgs.gov/>] and as a downloadable and printable one-page report with an accompanying description, such as that shown in Fig. 1.

Fundamental to such a system, the USGS NEIC operates the robust computational and communication infrastructure necessary for earthquake response. PAGER results are generally available within 20 min of a significant earthquake, shortly after the determination of its location and magnitude. However, information on the extent of shaking will be uncertain in the minutes and hours following an earthquake and typically improves as additional sensor data and reported intensities are acquired and incorporated into models of the earthquake's source. Users of PAGER should account for the inherent uncertainty in the initial PAGER estimates and be attentive to updates posted to the USGS web site.

The PAGER Process

In general, the shaking-related impact of an earthquake is controlled by the distribution and severity of shaking, the population exposed at each shaking intensity level, and how vulnerable that population is to building damage at each intensity level. Population vulnerability is dominated by the degree of seismic resistance of the local building stock. The PAGER system takes many such factors into account (Wald et al. 2010a, b). At the heart of PAGER are the timely and accurate earthquake location and magnitude determinations that the USGS has been producing for decades. PAGER uses these earthquake parameters to calculate estimates of ground shaking by using the methodology and software developed for ShakeMap (<http://earthquake.usgs.gov/shakemap/>). The ShakeMap system produces maps of regional ground shaking using a site-specific ground-motion amplification map, seismic wave attenuation equations, and

Earthquake Shaking **Orange Alert**

PAGER

Version 5

Estimated Fatalities

Orange alert level for shaking-related fatalities. Significant casualties are likely and the disaster is potentially widespread. Past events with this alert level have required a regional or national level response.

Yellow alert level for economic losses. Some damage is possible. Estimated economic losses are less than 1% of GDP of Ecuador.

Estimated Economic Losses

Estimated Population Exposed to Earthquake Shaking

ESTIMATED POPULATION EXPOSURE (k = x1000)	--*	115k*	5,238k*	5,971k	2,085k	1,767k	96k	0	0
ESTIMATED MODIFIED MERCALLI INTENSITY	I	II-III	IV	V	VI	VII	VIII	IX	X+
PERCEIVED SHAKING	Not felt	Weak	Light	Moderate	Strong	Very Strong	Severe	Violent	Extreme
POTENTIAL DAMAGE	Resistant Structures	none	none	none	V. Light	Light	Moderate	Moderate/Heavy	Heavy
	Vulnerable Structures	none	none	none	Light	Moderate	Moderate/Heavy	Heavy	V. Heavy

*Estimated exposure only includes population within the map area.

Population Exposure

Structures:

Overall, the population in this region resides in structures that are vulnerable to earthquake shaking, though some resistant structures exist. The predominant vulnerable building types are unreinforced brick masonry and mud wall construction.

Historical Earthquakes (with MMI levels):

Date (UTC)	Dist. (km)	Mag.	Max MMI(#)	Shaking Deaths
1979-03-01	31	5.7	VIII(4k)	0
1996-03-28	212	5.9	VIII(14k)	27
1987-03-06	245	7.1	IX(2k)	1k

Recent earthquakes in this area have caused secondary hazards such as tsunamis and landslides that might have contributed to losses.

Selected City Exposure

from GeoNames.org

MMI City	Population
VIII Muisne	13k
VIII Tosagua	15k
VIII Pedernales	6k
VII Bahia de Caraquez	37k
VII Rosa Zarate	42k
VII Chone	45k
VII Portoviejo	170k
V Guayaquil	1,952k
IV Pasto	382k
IV Quito	1,400k

bold cities appear on map

(k = x1000)

PAGER content is automatically generated, and only considers losses due to structural damage.

Limitations of input data, shaking estimates, and loss models may add uncertainty.

Event ID: us20005j32

Earthquakes, PAGER, Fig. 1 Example of the PAGER one-page summary product showing the color-coded impact scale indicated alert levels (top), the total population exposed per color-coded intensity level (center, near top), a map of the population density and contoured

intensity level (lower left), summary statements on country-specific structures and historical earthquakes (center right), and selected cities with population and intensity level (lower right)

recorded ground motions as well as reported intensities (Wald et al. 2005). The number of people exposed to each shaking intensity level is then calculated by combining the maps of estimated ground shaking with a comprehensive worldwide population database (Landscan, from Oak Ridge National Lab).

Next, based on the population exposed to each intensity level of shaking, the PAGER system estimates total losses based on country-specific models developed from economic and casualty data collected from past earthquakes (Jaiswal et al. 2009). To calibrate the loss models, the USGS has generated an atlas of approximately 6,000 ShakeMaps for significant global earthquakes that have occurred during the last 40 years (Allen et al. 2009). The calibration of loss methodologies relies on this atlas and on fatality and damage data aggregated or collected by the NEIC. Finally, the alert levels, determined by estimated ranges of fatalities and economic loss, are produced, with the higher of the two levels setting the overall alert level. The overall alert level determines which users are actively notified, and, at the same time, all PAGER information and content is automatically distributed to the web on the USGS Earthquake web pages, as part of the earthquake summary information, for immediate consumption.

The PAGER Earthquake Impact Scale

PAGER employs an earthquake impact scale (EIS, Wald et al. 2010a) that is based on two complementary criteria. One, based on the estimated cost of damage, is most suitable for domestic events; the other, based on estimated ranges of fatalities, is generally more appropriate for global events, particularly in developing countries. Simple thresholds, derived from the systematic analysis of past earthquake impacts and associated response levels, turn out to be quite effective in communicating the predicted impact and response needed after an event, characterized by alerts of green (little or no impact), yellow (regional impact and response), orange (national-scale impact and response), and red (international response). Corresponding fatality thresholds for yellow, orange, and red alert levels are 1, 100, and 1,000, respectively. For damage impact, yellow, orange, and red thresholds are triggered by estimated losses reaching \$1 million, \$100 million, and \$1 billion, respectively. The rationale for a dual approach to earthquake alerting stems from the recognition that relatively high fatalities, injuries, and homelessness dominate in countries where local building practices typically lend themselves to high collapse and casualty rates, and it is these impacts that lend to prioritization for international response. In contrast, it is often financial and overall societal impacts that trigger the level of response in regions or countries where prevalent earthquake-resistant construction practices greatly reduce building collapse and resulting fatalities.

Since PAGER calculations are available well in advance of ground-truth observations or news accounts, PAGER information can play a primary alerting role for domestic as well as international earthquake disasters. An example of the PAGER summary product, or *onePAGER*, for a destructive magnitude 7.8 earthquake in 2016 near the coast of Ecuador that killed several hundred people is shown in Fig. 1. This earthquake reached an orange alert level based on projected fatalities and a yellow alert level for economic losses. The alert level is based on the median loss estimate; the uncertainty in the alert level can be gauged by the histogram showing the percent likelihood that adjacent alert levels (or loss/fatality ranges) occur. Accompanying text clarifies the nature of the alert based on experience from past earthquakes and provides context on the total economic losses in terms of the percent of the gross domestic product (GDP) of the country affected.

Though PAGER uses simple and intuitive color-coded alerting criteria, it preserves the necessary uncertainty measures by which one can gauge the likelihood of adjacent alert levels. Utilizing the earthquake impact scale, PAGER's rapid loss estimates can adequately recommend alert levels and suggest appropriate response protocols, despite their uncertainties; demanding or awaiting observations or loss estimates with a high level of accuracy may increase the losses. Fig. 2 shows a global map of PAGER alerts over the past 10 years, since its inception in 2010. Over this time period, there have been 5,136 events with PAGER reports; of these, the final summary alert levels were 4,903 green; 175 yellow; 40 orange; and 18 red. This frequency equates to approximately 20 yellow, 3–4 orange, and 1–2 red alerts per year.

Ongoing PAGER Developments

USGS is improving the PAGER system to include losses from recent earthquakes, more comprehensive loss-estimate methodologies that take into account detailed building inventories that account for sub-country-level regional variations, more complete population demographics (including time of day occupancy shifts), and better tools to compute building damage (e.g., Jaiswal et al. 2010). Such data sets are very difficult and time consuming to acquire and are effectively unavailable in many areas of the globe. In particular, more detailed within-country building inventories are key for describing the dominant vulnerable structures that contribute to casualties in the region. Knowledge of the main collapse “culprits” is vital for response, public safety, recovery, and long-term mitigation. The USGS PAGER team is working with the Global Earthquake Model (GEM) Foundation to refine and calibrate both the PAGER and GEM national loss models for improved real-time loss estimates.

Related USGS developments under the auspices of the PAGER project include rapid determination of fault

Earthquakes, PAGER, Fig. 2 Summary map showing PAGER alerts from its initial deployment in September 2010 through March 2019. Alerts shown are the maximum of the economic or fatality alert for each event

geometry, size, and rupture characteristics, refined global estimates of seismic soil-amplification patterns, ShakeMap enhancements, and ground-motion and loss-uncertainty analyses. Ultimately, the PAGER system will also directly incorporate impact estimates due to earthquake-induced landslide and liquefaction, integrating ground failure probability products that are maturing to the point of near-real-time operational use (Allstadt et al. 2016). Other strategies for improving rapid loss estimates include ongoing efforts to condition loss estimates on ground-truth loss data as they become available and the use of satellite imagery to refine damage locations and locations of ground failure and to improve upon modeled loss estimates themselves.

Summary

The Prompt Assessment of Global Earthquakes for Response (PAGER) system provides rapid (less than 20 min) post-earthquake information concerning the impact of significant earthquakes within approximately 20 min of any magnitude 5.5 or larger event around the world. PAGER has been operating automatically for nearly a decade, starting in 2010, and produces approximately 20 yellow, 3–4 orange, and 1–2 red alerts per year. These color-coded alerts, tied to the higher of the likely fatalities or economic losses (see Fig. 1), are widely used for response decision-making.

PAGER rapidly assesses earthquake impacts by comparing populations exposed to estimates of shaking intensity and models of economic and fatality losses based on past earthquakes in each country or region of the world. The main PAGER output – a one-page summary document – is sent to thousands of emergency responders, government and aid agencies, and the media to the scope of the potential disaster. In addition, PAGER loss estimates and information products are also fully integrated into the USGS Earthquake Information “event page” automatically generated for all earthquakes detected by the USGS. This impact summary information is available on the USGS earthquake web pages and as a printable, one-page report with accompanying descriptions such as those shown in Fig. 1.

Earthquakes, ShakeCast

Kuo-wan Lin, David J. Wald and Daniel Slosky
U.S. Geological Survey, Denver Federal Center, Lakewood,
CO, USA

Definition

ShakeCast[®] – short for *ShakeMap Broadcast* – is a fully automated software system for delivering specific ShakeMap products to critical users and for triggering established post-earthquake response protocols. ShakeCast is a freely available, postearthquake situational awareness software application that automatically retrieves earthquake shaking data from ShakeMap to compare ground shaking intensity measures against users' facilities (Lin and Wald 2008; Lin et al. 2018). ShakeCast then generates potential damage assessment and inspection priority notifications, maps, and web-based products for critical users, emergency managers, and those on a need-to-know basis.

Background

When a potentially damaging earthquake occurs, emergency actions are needed to ensure safety, restore system functionality, and minimize losses. Situational awareness in the immediate aftermath of a disastrous earthquake is of fundamental importance for an effective societal response. While overall disaster management is critical, a successful, organized response is dependent on the collective efforts of the community at large. Businesses, utilities and critical lifeline managers, emergency responders, and a wide variety of other parties have an urgent need for information so they can

make informed decisions and take quick actions. ShakeCast allows such groups to control and optimize the earthquake information they receive. With ShakeCast, they can automatically determine the shaking value at *their* facilities, set thresholds for notification of damage states for each facility, and automatically notify (via cell phone or email) specified operators, inspectors, etc., within their organizations who are responsible for those particular facilities so they can prioritize response.

ShakeMap is a well-established tool for portraying the extent of potentially damaging shaking following an earthquake (Wald et al. 1999; Worden and Wald 2016). ShakeMaps are automatically generated for both small and large earthquakes and can be found online at <http://earthquake.usgs.gov/shakemap>. The ShakeMap system was developed and is used for emergency response, loss estimation, and public information. However, for an informed response to a serious earthquake, critical users must go beyond just ShakeMap to understand the likely extent and severity of impact on the facilities for which they are responsible. In order to facilitate the use of ShakeMap for critical preearthquake planning and postearthquake response, USGS has developed ShakeCast.

ShakeCast is deployed by public and private emergency responders, lifeline operators, and facility engineers to automatically receive and process ShakeMap products for situational awareness, inspection priority, or damage assessment. For example, the California Department of Transportation (Caltrans) utilizes ShakeCast to identify bridges and buildings that require damage inspections following an earthquake, with more than 24,820 state and local bridges and facilities cataloged in their ShakeCast system. There are 568 groups and individuals within Caltrans who receive emails within 10 min of an earthquake of magnitude 4.0 and greater occurring in California. Caltrans can then respond quickly to potentially damaging incidents and focus inspection efforts where needed, better protecting the transportation network. Figure 1 is an example of the ShakeCast product that is automatically sent to users as a quick summary of the situation, including which facilities need to be inspected first.

Caltrans' ShakeCast system routinely sends notifications to Caltrans responders for all earthquakes greater than M4.0 that have resulted in significant ground shaking within California; over 300 events were evaluated in the past decade. Though widely felt in the region and reported through the media, the vast majority of these earthquakes did not produce ground shaking strong enough to cause damage to Caltrans structures. A few events, however, have generated significant shaking and triggered ShakeCast "Potential Impact" notifications: the 2008 M5.4 Chino Hills, 2010 M7.2 Calexico, and 2014 M6.0 Napa earthquakes. For each, ShakeCast generated messages to responders and damage to bridges was observed.

Earthquakes, ShakeCast, Fig. 1 Example of the ShakeCast report for a rerun of the 1994 magnitude 6.7 Northridge, California earthquake created for testing and calibration purposes for the California Department of Transportation (Caltrans). This is a standard ShakeCast product,

which gives a visual overview of the facility locations and ShakeMap shaking levels above a summary of the facility (bridge and overpass) locations, inspection priorities, and shaking levels

ShakeCast System Overview

The goal of the ShakeCast system is to provide simplified, near-real-time damage and inspection metrics in order to facilitate users' inspection priorities and response protocols (green, yellow, orange, and red priority ratings). Building or bridge fragilities can be evaluated for potential damage level and likelihood within ShakeCast using individual ShakeMap intensity measures (specifically, Modified Mercalli Intensity (MMI), peak horizontal ground acceleration (PGA), peak horizontal ground velocity (PGV), and 0.3, 1.0, and 3.0 s spectral accelerations) for each facility (Worden and Wald 2016).

The ShakeCast application is built upon open-source (Python) code, providing standard, freely available software for all users. All ShakeMap and ShakeCast files and products are nonproprietary to simplify interfacing with existing users' response tools and to encourage user-made enhancement to the software. ShakeCast software development utilizes the GitHub framework for both code distribution and documentation. Any GitHub user can contribute to the development of the ShakeCast application or submit feature requests in the form of "issues." Most users of ShakeCast operate the software in a cloud computing environment. During the development of ShakeCast, a conscious decision was made to provide

the software to critical users to run their own response operations in-house, rather than providing a centralized service (like ShakeMap), for a number of reasons. First, a user's inventory may be proprietary and thus analyses must be made in-house. Second, for a large and changing inventory, the user is more likely to keep an up-to-date database, and it would be unproductive for USGS to take on such a role. Finally, users can customize damage functions, modify recipient contact information, and customize who receives notifications, what they receive, and under what conditions, at their convenience.

Initial ShakeCast setup involves (1) populating a database of facility locations and types, (2) assigning fragilities using specific ShakeMap parameters (e.g., intensity, peak or spectral acceleration) and the corresponding likely "green," "yellow," and "red" damage states (such as "damage unlikely," "damage possible," and "damage likely" thresholds), (3) specifying who receives notifications by listing addresses of facility managers and response personnel (email, cell phone), and (4) selecting under which circumstances the alerts are sent (e.g., "damage possible" at specific facilities). Users can also customize the content of the summary report that is delivered internally, for example, adding organizational-specific links and images, or listing facilities based on their likely damage state.

Earthquakes, ShakeCast, Fig. 2 Distribution of shaking hazards from the USGS and State transportation department partners in the Transportation Pooled Fund. Ten state Departments of Transportation

(DOT) – CA, ID, MO, MS, OK, OR, SC, TX, UT, and WA – have partnered with the USGS ShakeCast team

Earthquakes, ShakeCast, Fig. 3 USGS ShakeMap earthquake scenario portal for events in the continental USA. Any such scenario can be imported into ShakeCast to evaluate effects on facilities for training exercises or evaluating capacity to respond

Whereas many ShakeCast users host their own ShakeCast software and operations (a ShakeCast “instance”), many life-line, government agencies, and other large groups – who could benefit from operating ShakeCast – have difficulty running and maintaining a 24×7 software application in-house. Thus, USGS converged on ShakeCast software variations with two main options, in-house and remote (USGS operated) ShakeCast software instances. *ShakeCast Remote* has become an option for hosting multiple instances of the software using a single server to take advantage of the dynamic scaling of server provision in a modern virtualization environment. For example, a USGS-hosted ShakeCast server for the Transportation Pooled Fund, a consortium of a dozen State Department of Transportation (Fig. 2; Turner et al. 2018), is an example of such a deployment, utilizing one to a dozen instances. Such ShakeCast instances are running in their own confined domain with the full features of ShakeCast, operated remotely by the USGS, sending alerts and notifications to the appropriate recipients dependent on the region of any earthquake.

Outlook

The ShakeCast development team coordinates with the ShakeMap team to bring upgrades and features to end users.

Several upgrades to the USGS ShakeMap system are noteworthy, particularly as they pertain to ShakeCast. Improvements have been made to (1) event-specific metadata, product archiving, and technical documentation; (2) additional gridded parameters (including interpolated rock-motion shaking estimates); and (3) ground motion interpolation, including spatial variability characterization and directivity functions (Worden and Wald 2016).

In addition to real-time notification, ShakeCast can also generate and deliver scenario earthquakes for facility response plans and earthquake drills or exercises. This includes routine testing of the system, earthquake scenario exercises, and evaluating performance and response under potential earthquake conditions. A new online catalog of more than 900 ShakeMap earthquake scenarios includes the deterministic ruptures from the 2014 version of the USGS national seismic hazard model. The systematic collections of ShakeMaps regarding event selection, ground motion prediction equations (GMPEs), and site response provide more opportunities for ShakeCast testing and evaluation (Fig. 3).

Earthquakes, ShakeMap

David J. Wald, C. Bruce Worden, Eric M. Thompson and Michael Hearne
U.S. Geological Survey, Denver Federal Center, Lakewood, CO, USA

Definition and Introduction

ShakeMap[®] is an open-source software program employed to automatically produce a suite of maps and products that portray the geographical extent and severity of potentially damaging shaking following an earthquake. ShakeMap's primary purpose is to provide post-earthquake situational awareness for emergency management and response as well as damage and loss estimation. The availability of ShakeMaps immediately after a significant earthquake is critical for the identification of areas likely to be most damaged. Principal users include first responders, utility companies, response and aid agencies, scientists and engineers, and the media. Maps are made publicly available via the Internet within several minutes of an earthquake's occurrence. ShakeMap is widely deployed in seismically active, well-instrumented portions of the USA and internationally in numerous countries including Italy, Iceland, Greece, Costa Rica, and Switzerland, among others, and the US Geological Survey's (USGS) global system provides approximate maps for all earthquakes of magnitude 5.5 and larger worldwide.

Making a ShakeMap entails deriving a detailed description of the shaking over a large region by integrating a variable distribution of seismic stations and macroseismic intensity data. This requires intelligently guided interpolation of measured and estimated ground motions unless the measured

recordings are extremely abundant (as in Japan, for instance). In the ShakeMap algorithms, empirically based ground-motion estimates, modified by simple geologically based, frequency- and amplitude-dependent site-correction factors, provide useful first-order shaking constraints to guide interpolation in areas that are not well instrumented. Thus, essential elements of a ShakeMap system include (1) near-real-time peak ground motion and/or intensity observations; (2) a ground-motion site-amplification map for the region; (3) the ShakeMap algorithms, which combine and guide interpolation of ground-motion observations with built-in shaking estimates (Worden et al. 2018) to produce the suite of shaking-hazard maps; and (4) mechanisms for automatically transferring ShakeMap products to users, including via interactive web pages and through Internet-based product feeds. For larger events (magnitude greater than 7.0), ShakeMap also uses a description of the fault that ruptured during the event, though this often takes hours to characterize so it is added to later revisions of the maps.

An example ShakeMap for the 2014 magnitude 6.0 South Napa earthquake just north of San Francisco, CA, that employs data from seismic stations from the California Integrated Seismic Network (CISN) is shown in Fig. 1. The ShakeMap shaking pattern is well-constrained at and near seismic stations (triangles in Fig. 1) and macroseismic observations (circles in Fig. 1), and the shaking pattern is less well-informed elsewhere. Station locations thus provide a sense of how well-constrained the shaking is in any region of a ShakeMap. The seismic station and macroseismic observation data in aggregate also help provide an overall fit to the data by informing the modeled shaking of overall trends. Whether showing the signature ShakeMap product – the image of shaking intensity (Fig. 1) – or contours of other shaking parameters like PGA (Fig. 2), the overall goal of ShakeMap is to provide a recognizable depiction of the areas of the strongest shaking for any earthquake.

Historical Context

The most common information available immediately following a damaging earthquake has traditionally been magnitude and hypocenter location. However, the damage pattern is not a simple function of these two parameters alone, and more detailed information is necessary to properly evaluate the situation. ShakeMap fills this role, and it has proven to be a useful, descriptive display for rapidly assessing the scope and extent of shaking and potential damage following an earthquake. Because large earthquakes are generated over a fault surface, not at a single point, the location of the earthquake (the epicenter) tells us only where the earthquake started, not necessarily where the shaking was the greatest. For a large earthquake, damage can occur hundreds of miles from the epicenter (e.g., see Fig. 3). Other factors – such as rupture

Earthquakes, ShakeMap, Fig. 1 Intensity ShakeMap for the magnitude 6.0 South Napa, California, earthquake of August 24, 2014. Triangles indicate locations of seismic stations, and circles show observed macroseismic observations contributing to the map, each color-coded to

the intensity scale shown below the map. The surface projection of the fault trace is shown with a black line connected to the epicenter (black star)

direction, underground earth structure, and shallow geology – influence the amount of shaking in a particular area. For example, although emergency responders identified many areas of heavy damage soon after both the 1994 Northridge and the 1989 Loma Prieta, California, earthquakes, additional regions of severe damage were only belatedly discovered. A ShakeMap displays the distribution of ground shaking within minutes after an earthquake so that emergency managers can properly deploy resources to those locations with the greatest potential damage.

Part of the strategy in designing rapid-response ground-motion maps was to determine the best format for reliable

presentation of the maps, given the diverse audiences. In an effort to simplify and maximize the flow of information to the public, ShakeMap was designed to produce not only peak-ground acceleration and velocity maps used by engineers but also an instrumentally derived, estimated Modified Mercalli Intensity map. The color-coded instrumental intensity map makes it easier to relate the recorded ground motions to the felt experience and damage distribution (e.g., Fig. 1). ShakeMap was first developed for earthquakes in Southern California as part of the TriNet Project, a joint effort by the USGS, the California Institute of Technology, and the California Geological Survey (Wald et al. 1999). Following the

Earthquakes, ShakeMap, Fig. 2 Peak ground acceleration (PGA) contour ShakeMap for the magnitude 6.0 South Napa, California, earthquake of August 24, 2014. Contours show PGA in percent g. Symbology is the same as in Fig. 1

Northridge earthquake, older analog instruments were replaced with a modern seismic network employing near-real-time digital communications. A by-product of that improved network, ShakeMap was further enhanced by advances in telecommunications and computer-processing speed, as well as research that improved empirical ground-motion predictions and the relations among recorded ground motions and shaking intensities. A prototype ShakeMap system was first deployed in Southern California in 1997; refinements to the ShakeMap system continue today (e.g., Worden et al. 2018).

Related Systems and Uses

ShakeMap has facilitated the development and implementation of additional post-earthquake analyses and tools. Separate map layers are generated, each comprised of the spatial distribution of a specific peak ground-motion parameter

(specifically acceleration, velocity, or response-spectral acceleration) as well as a layer for instrumentally derived seismic intensities. In addition to maps, ShakeMap produces a grid containing the value of each parameter, as well as geographic information system (GIS) files and a host of other products intended for a variety of other uses and users. In particular, peak ground motion and spectral acceleration are fundamental parameters for earthquake-engineering and loss-estimation analyses; these gridded parameters of shaking can be combined with building inventory or lifeline databases to rapidly produce maps of estimated damage. All the ShakeMap products and formats can be automatically retrieved via GeoJSON feeds and other web services (Worden et al. 2017).

One commonly used loss-modeling approach, both for post-earthquake response and pre-earthquake mitigation, is the Federal Emergency Management Agency's (FEMA) Hazards US (HAZUS) software. FEMA routinely uses HAZUS to compute earthquake losses based on ShakeMap input within the United

Earthquakes, ShakeMap, Fig. 3 ShakeMap depiction of the shaking pattern experienced during the Great 1906 San Francisco earthquake. Since there were no digital seismic stations at the time, we rely on reported macroseismic observations (circles) that provide not only

constraints of the intensity at their locations but they also allow for estimates of the peak ground motions by employing the intensity to ground-motion conversion equations of et al. (2012). The 1906 rupture on the San Andreas Fault is shown as a black line

States. A secondary system for ShakeMap, ShakeCast[®] (short for ShakeMap Broadcast) is a fully automated system for delivering specific ShakeMap products to critical users and for triggering established post-earthquake response protocols (Lin and Wald 2008). ShakeCast allows utility and transportation agencies, businesses, and other large organizations to control and optimize the earthquake information they receive. With ShakeCast, users can automatically determine the shaking value at their facilities, set thresholds for notification of different degrees of damage for each facility, and then automatically notify (via text or email) specified operators, inspectors, or responders within their organizations who are responsible for those particular facilities so they can prioritize response. For example, via ShakeCast, the California Department of Transportation (Caltrans) can prioritize inspection of thousands of bridges and overpasses statewide, an otherwise potentially overwhelming task.

Another secondary system, also developed primarily as a by-product of the USGS global implementation of ShakeMap, is called PAGER (Prompt Assessment of Global Earthquakes for Response). PAGER combines shaking intensity with exposed populations to rapidly and automatically estimate economic and human impacts worldwide (Wald et al. 2010). Unlike regional ShakeMap systems that rely on dense instrumentation, the global ShakeMap system relies primarily on the predictive aspects of the ShakeMap system; it incorporates site amplifications based on approximate soil conditions derived from topographic slope and utilizes macroseismic intensity data, if available, from near-real-time, Internet-based data collection systems such as the USGS “Did You Feel It?” system (Wald et al. 2011).

ShakeMaps also now provides the shaking constraints needed to rapidly estimate the likelihood and distribution of landslides and liquefaction for earthquakes around the globe (Allstadt et al. 2016). These secondary earthquake-shaking-induced ground failures can contribute substantially to earthquake losses and complicate post-earthquake response, particularly when they occur along transportation corridors.

Though developed primarily for post-earthquake, near-real-time situational awareness, ShakeMap algorithms, which incorporate empirical ground-motion estimation capabilities, are widely used for other purposes. One side-benefit of the built-in ability to estimate ground motions for a specified earthquake is generating hypothetical earthquake ground-motion maps. Such “Scenario ShakeMaps” are useful for response planning and long-term earthquake mitigation, since portraying the overall pattern of shaking for potential future events is useful for earthquake drills and loss assessments. Hundreds of USGS ShakeMap scenarios are available on the USGS ShakeMap web site (<http://earthquake.usgs.gov/shakemap/>). Calibration of earthquake loss models is facilitated by creating ShakeMaps for historical earthquakes, which has been done for significant earthquakes around the globe from

1970 to recent (the ShakeMap Atlas; Allen et al. 2009; Garcia et al. 2012). Some of these historic ShakeMap events have constraints from ground motion, intensity, and fault extent; others are purely predictive. Nonetheless, such historic ShakeMaps can be used for loss calibration or for better scientific understanding of the nature of past earthquakes.

For example, though the magnitude 7.8 of 1906 San Francisco earthquake occurred in the pre-digital instrumentation era, the widespread shaking experienced and the damage observed were well-documented. Macroseismic intensities were assigned both at the time and more recently by revisiting historic accounts in newspapers and other archives of that period (Boatwright and Bundock 2008), providing ample data for producing an informative ShakeMap (Fig. 3).

Summary

Over the past two decades, rapid earthquake information has evolved from providing a magnitude and location to depicting the variations of the intensity of shaking over the region potentially affected by each earthquake. The standard approach to depicting shaking is now with the ShakeMap system, which allows the best estimates of shaking intensity and other peak ground-motion parameters (including peak acceleration, peak velocity, and spectral acceleration at various periods).

The shaking estimates in ShakeMap are computed by a logical, weighted combination of shaking estimates, recorded ground motions, and reported or assigned macroseismic intensities over the area of interest. Often the estimated motions are strongly influenced by the dimensions of the fault that rupture, so rupture finiteness is properly taken into account as soon as that information becomes available, typically a few hours or so after a major earthquake.

ShakeMap is used for a variety of purposes, primarily for post-earthquake situational awareness. As such, many ShakeMap formats are provided via the USGS Earthquake Program web pages and data feeds that include geospatial grids, station files, faults, GIS, KML, GeoJSON, and all the metadata needed to follow changes to ShakeMaps since they often evolve as more data become available. However, historic and scenario ShakeMaps are widely used for planning and mitigation purposes so that responders can plan ahead.

Definition

Strong-ground motion An earthquake-induced ground motion capable of damaging man-made environment.

Introduction

Earthquake ground motion is a natural phenomenon associated with a sudden release of energy due to a fault rupture. Strong-motion seismology deals with seismic waves radiated by large earthquakes. More precisely, it is concerned with measurement, interpretation and prediction of strong shaking generated by damaging earthquakes.

Because of the engineering need for estimates of future strong-ground motion, the scope of strong-motion seismology encompasses seismic source theory and all other aspects of seismology that can provide insights helpful in making the best possible earthquake ground-shaking scenarios given the limited observational data.

Accumulated data have been providing very important knowledge about rupture processes of earthquakes, propagation paths and site effects on ground motion, and the relation between ground motion, damage, and other earthquake related phenomena (e.g., landslides earthquake induced).

The most important goals of strong-motion seismology are the improvement of the physical understanding of the processes controlling strong-ground motion and the reliable assessment of seismic hazard.

To assess the hazard for engineering design applications and due to the limited availability of strong-ground motion records, it has become increasingly common to compute broadband synthetic seismograms that allow us to perform realistic waveform modeling for different seismotectonic environments. The modeling has to take simultaneously into account the properties (e.g., dimensions, directivity, and near-field effects) of the radiating source, lateral heterogeneities along the path, and local site effects.

The joint use of reliable synthetic signals and observations can be fruitfully used for design purposes. In fact, even if recently strong-motion records in near-fault, soft soils, or basin conditions have been obtained, their number is still very limited to be statistically significant for seismic engineering applications.

The lack of a representative set of observations is due to the low frequency of large earthquakes and to the difficulty of providing a proper instrumental coverage of all the areas prone to strong shaking. Despite of the growing strong-motion registration networks, the existing database is still not complete with respect to the possible scenario earthquakes, and the lack of completeness will last for many years if not centuries. The variability of ground motion, due to different causes, e.g., spatial variability, source parameter variability, azimuthal variability (Strasser and Bommer 2009), show how the current available strong-motion data still represent only a small sample of all physically possible ground motion. The mathematical modeling, with different degrees of complexity, based on probabilistic concepts cannot

fill in the gap due to the lack of knowledge about the physical process behind an earthquake (Panza et al. 2004). Therefore, to resort to broadband synthetic seismogram is a fundamental step: where no records are available, synthetic signals can be used to estimate the ground motion without having to wait for a strong earthquake to occur.

Description of Strong-Ground Motion

A seismic record of ground acceleration, due to a damaging shaking, is usually defined a strong-motion datum. There is not a quantitative rule, but it is generally assumed that damaging earthquakes are those of magnitude 5 and above. The threshold to be exceeded in terms of peaks acceleration for ground motion to be considered strong motion is quite blurred. The strongest recorded earthquake motions have peaks between 1 and 3 g, but these are very rare events. Usually, damages are caused by ground motion, which exceeds the threshold of 0.1 g, but Bolt and Abrahamson (2003) lower this limit to 0.05 g.

Due to the importance of strong motion for earthquake engineering, a number of different parameters have come into use to represent various characteristics of strong motion. Actually, the most appropriate way to describe or specify the characteristics of ground motion for the purpose of seismic design is still an open problem. A large number of parameters have been proposed for measuring the capacity of earthquakes to damage structures. However, to account for the complex characteristics of earthquake-induced strong-ground motion in the engineering analysis and design, the need arose for a more inclusive definition of the existing parameters and for the introduction of new ones. In fact, the adoption of inadequate parameters can lead to the definition of unrealistic design earthquakes and consequently to the unreliable evaluation of the seismic risk.

The parameters fundamentally involved in the evaluation of the level of severity associated with strong motion are, for engineering purposes, the frequency content, the amplitude, and the effective duration.

Beginning about the 1960s, the most used ground-motion parameter for quantification of ground motion was the peak ground acceleration (PGA), as the inertia forces depend directly on acceleration. PGA is simply obtained from unprocessed accelerograms. However, PGA is a poor indicator of damage, since, as observed, time histories with the same PGA could be very different in their frequency content, strong-motion duration, and energy level. In fact, PGA may be associated with high frequency pulses, which do not produce significant damage to the buildings as most of the impulse is absorbed by the inertia of the structure with little deformation. On the other hand, a more moderate acceleration may be associated with a long-duration pulse of low

frequency (acceleration pulse), which gives rise to a significant deformation of the structure. The peak ground velocity (PGV) is another useful parameter for the characterization of ground-motion amplitude. The velocity is less sensitive to the higher-frequency components of the ground motion, so the PGV should be more useful than the PGA in characterizing the damaging potential of ground motion. For design purposes, the peak ground displacement (PGD), generally associated with the lower-frequency components of an earthquake ground motion, has been recognized as useful parameter, mostly for the design of seismically isolated structures.

The response spectrum, firstly proposed by Benioff (1934), defined as the maximum response of a damped harmonic system to input motion (Anderson 2003), is a parameter widely used for engineering purposes.

Another ground-motion parameter, very important for engineers, is the duration of shaking (Villaverde 2009). Duration can impact structures and response of soils: structures that can stand one or two large oscillations may collapse under prolonged motions, and while a second of shaking of sandy soil can be tolerated, repeated oscillations can induce liquefaction (Jennings 2003). But there is not a unique definition of duration, as clearly evidenced in Bommer and Martinez-Pereira (1998), where 30 definitions of strong-motion duration are reported. The available definitions can be classified in three different groups, or as a combination of them (Montejo and Kowalsky 2008): (1) “bracketed” durations (Bolt 1969), in which the duration is defined to be the time interval between the first and the last exceedances of a threshold of acceleration; (2) “significant” durations that define the duration of strong motion as the time interval during which a given percentage of the total energy of the record is released; and (3) frequency-dependent durations, in which the duration of strong-ground motion is analyzed separately in several narrow-frequency bands (Bolt 1969; Trifunac and Westermo 1977). The following two examples of duration measurement show the limits of this parameter. A way to estimate duration is to measure the interval of time within which acceleration exceeds some threshold, usually 0.05 g (bracketed duration, Bolt 1969); another measure is the interval of time in which 90% of the integral of the acceleration-squared is recorded. These two estimations yield opposite results as the distance from the source increases. Peak ground motions decrease, as a rule, with increasing distance from the source (for exceptions, see e.g., Panza and Suhadolc 1989; Fah and Panza 1994), but energy becomes dispersed, so the time that is necessary to wait for the arrival of the 90% of the total energy in the seismogram increases (Anderson 2003).

Several equations, commonly referred to as attenuation relations or ground-motion prediction equations (GMPE), have been proposed over the years from strong-ground motion observations and theoretical studies. These

mathematical expressions give ground-motion intensity measures as a function of earthquake magnitude and distance. They may be determined empirically, by a regression of recorded ground motion, or theoretically, using seismological models to generate synthetic ground motions that account for the source, site, and path effects. Theoretical attenuation relations between various source parameters are used to estimate source parameters for earthquakes that have not yet occurred, or for which parameters of interest are unknown (e.g., Geller 1976; Oth et al. 2007; Somerville et al. 1997). The other approach uses empirical relations between source parameters compiled for a huge number of earthquakes (e.g., Wells and Coppersmith 1994). In the past few years, the availability of additional strong-motion data has allowed the incorporation of additional parameters, such as type of fault, fault orientation; further recent relationships have increasingly become more refined, although, at the same time, more complicated. Attenuation relations are usually grouped into three sets (Panza et al. 2004): shallow crustal earthquakes in active tectonic regions, shallow crustal earthquakes in stable tectonic regions, and subduction zone earthquakes. These relations can differ in the assumed functional form, the data selection criteria, the number and definition of independent variables, and the statistical treatment of the data. A review can be found in Douglas (2003), where the complete procedure that needs to be followed to derive equations for the estimation of ground motion from recorded strong-motion data is outlined as well. As the coefficients of the attenuation relations are determined empirically by means of regression analysis, they are quite sensitive to the used data set, an example of the dependence of attenuation relations on the procedure followed in the data processing is given by Parvez et al. (2001) for the Himalayas. The Izmit, Turkey, earthquake of August 17, 1999 and the Chi Chi, Taiwan, September 20, 2000, did show the inadequacy of the existing database: as explained in Anderson (2007), the GMPEs available at that moment underestimated the peak accelerations for those events. The discrepancies could be due to a wide variety of factors, so these examples suggest that a large amount of data and a deep physical understanding of the processes involved in seismic events are needed to improve the quality of GMPEs (Anderson 2007). A common main source of error can be mathematical shortcomings that arise when attenuation relations are used in geologically complex areas (e.g., Peresan et al. 2010).

As stressed earlier by Aki: “a major goal of strong-motion seismology is to be able to synthesize strong-motion seismograms suitable for use in engineering analysis” (Anderson 2003, p. 942). The use of computational modeling has the aim to simulate the wave generation and propagation process in complex media. The formulation of physical-mathematical models aimed to represent the effective complexity of the phenomenon and their resolution is a

complicated affair. With the exception of a very limited number of simple situations, the physical-mathematical approach does not lead to closed form solutions, i.e., fully analytical, so it is necessary to employ numerical procedures, more or less complex, or approximated theories (Bolt 1999).

Earthquake Source Effects on Strong-Ground Motion: Near-Field Effects

Source effects on far-field seismograms are discussed by Aki and Richards (1980, Chap. 14). Seismic data used in earthquake engineering are occasionally collected in the near-field, but the question where the near-field ends and the far-field begins is gradational and will not be addressed here.

Near-fault ground motions often contain large long-period pulses (Somerville 2002). There are two causes for these pulses: one is constructive interference of the dynamic shaking due to rupture directivity effects, the other is due to the movement of the ground associated with the permanent offset of the ground. For keeping these two causes separated, the terms “directivity pulse” and “fling step” have been introduced (Bolt and Abrahamson 2003).

Large earthquakes are produced by rupture that starts at a point and travels with a velocity that is generally only slightly smaller than the shear-wave velocity in the medium. Therefore, when rupture is towards the station, the propagation causes most of the seismic energy to arrive in a single large pulse occurring at the beginning of the record. Forward-directivity effects occur when the rupture front propagates towards the recording site and the slip direction on the fault is aligned with the site. Backward-directivity effects, occurring when the rupture front propagates away from the recording site, generates opposite effects, i.e., longer-duration motions, lower amplitudes, and longer periods. This phenomenon has been first explained by H. Benioff in 1955, when analyzing the records of the 1952 Kern County, California, earthquake. The conditions for generating forward-rupture directivity effects are readily met in strike-slip faulting, where the rupture propagates horizontally along the strike either unilaterally or bilaterally, and the fault slip direction is oriented horizontally in the direction along the strike of the fault. As described by Bolt and Abrahamson (2003), for strike-slip earthquakes, the rupture directivity is observed on the fault normal component, and the static displacement fling step is observed on the fault parallel component. The conditions required for forward directivity are also met in dip-slip faulting, including both reverse and normal faults. The alignment of both the rupture direction and the slip direction up dip on the fault plane produces rupture directivity effects at sites located around the surface exposure of the fault (or its up dip projection if it does not break the surface). Consequently, it is generally the case that all sites located near the surface

exposure of a dip-slip-fault experience forward-rupture directivity when an earthquake occurs on that fault.

For dip-slip earthquakes, the separation of the effects (rupture directivity and fling step) on the fault components is more complicated: the rupture-directivity effect will be strongest on the fault normal component at a location direct up-dip from the hypocenter, and the fling-step will also be observed on the horizontal component perpendicular to the strike of the fault, i.e., directivity-pulse effects and fling-step effects occur on the same component for dip-slip faults. The horizontal records of the 1966 Parkfield and 1971 San Fernando, California, earthquakes were the first to be discussed (Bolt 1975) as examples of near-fault velocity pulses. The pulses from both directivity and fling-step may attenuate differently. Hisada and Bielak (2003) investigated the combined effects of fling-step and rupture directivity by paying special attention to the contribution of static and dynamic Green's functions. Fling effects are found to be stemmed mainly from the static Green's function. They are dominant in the vicinity of the surface fault and negligible for buried faults since the static Green's function decreases rapidly, as $(1/r^2)$, with the distance from the fault. When the observation point is above the buried fault, the fling step disappears because the slip dislocation of the fault cannot fling the ground, due to the presence of a continuous medium above the fault itself. Directivity effects derive mainly from the dynamic Green's function and attenuate as $(1/r)$ to $(1/\sqrt{r})$, more slowly than the fling. The combination of both the effects of rupture directivity and fling-step results in inclined directions, with respect to the fault plane, of maximum velocities, and displacements.

The destructive potential of near-fault ground motions was manifested in the 1994 Northridge and 1995 Kobe earthquakes. In each of these earthquakes, peak ground velocities as high as 175 cm/s were recorded. The period of the near-fault pulses recorded in both of these earthquakes lies in the range from 1 to 2 s, comparable with the natural periods of structures, such as bridges and buildings, many of which were indeed severely damaged.

Near-fault recordings from recent earthquakes indicate that this pulse is a narrow band pulse whose period increases with magnitude. This magnitude dependence of the pulse period causes the response spectrum to have a peak whose period increases with magnitude, such that the near-fault ground motions from moderate-magnitude earthquakes may exceed those of larger earthquakes at intermediate periods (around 1 s).

Wave-Propagation Effects

Wave propagation in heterogeneous media is addressed in another chapter herein (see ► [“Propagation of Elastic Waves: Fundamentals”](#)), so, here we limit the analysis to site effects due to their impact on strong-ground motion.

Ground motion can be highly amplified, or deamplified, by local effects. The essential aspects of site effects on strong-ground motion are widely addressed in literature (see e.g., Kawase 2003). The pioneering works where site effects are well-recognized date back to 1930s and are due to Sezawa and Ishimoto (Kawase 2003), but a first comment on the effect of near-surface conditions on shaking intensity during the 1906 San Francisco earthquake dates back to 1910: “Experience shows that the damage done by destructive earthquakes is much greater on alluvial soil than on solid rock” (Reid 1910). Almost all recent destructive earthquakes have shown the relevance of site effects in the amplification of the seismic ground motion. The classical example of such a situation is the September 19, 1985 earthquake that, in Mexico City, about 400 km far away from the epicenter, caused a large victims toll (about 8000), destroyed or heavily damaged hundreds of buildings, and caused few billion dollars damage (Fah et al. 1994; Anderson et al. 1986). The presence of lacustrine sediments is the cause of the large ground motion, up to 40 times larger than that of firm ground (Chávez-García and Salazar 2002). The modeling of wave propagation in basins, and more generally in complex 2D and 3D regions, using numerical methods, such as finite difference (FDM), finite element (FEM), spectral element method (SEM), boundary integral equation, and boundary element method (BIEM and BEM) is an active field of research (see e.g., Aagaard et al. 2001; Bielak et al. 1991; Bouchon and Sánchez-Sesma 2007; Graves 1996; Komatitsch and Tromp 1999, 2002a, b; Komatitsch and Vilotte 1998; Komatitsch et al. 2004; Oprea and Zahradnik 1999, 2002; Pitarka 1999; Yoshimura et al. 2003). These methods differ in accuracy with respect to different structural features of the complex heterogeneous models and considerably in the computational efficiency. For comparison of several modeling methods, we refer to the review paper by Takenaka et al. (1998), but the most recent review of the computational and numerical modeling methods can be found in the book edited by Wu and Maupin (2007). Very recently, a new analytical approach has been developed and validated performing simulations in the area of the Kanto basin, Japan (La Mura et al. 2010). It is generally observed that at stations throughout the basin larger amplitudes and longer durations of ground shaking are observed, but the pattern can be very complicated. The amplification patterns depend not only on the site conditions, but also on the characteristics of the incoming wavefield and, therefore, on the source and the wave propagation path. Clear examples are given in Field (2000).

Last but not least, we mention the liquefaction phenomenon, largely observed, for example, during the Niigata earthquake, Japan, on June the 16th, 1964 (Youd 2003; Bardet 2003). Liquefaction of water-saturated sands is believed to occur when the pore pressure, increased by the strong-ground motion, reaches the effective confining pressure. The

likelihood that an earthquake will liquefy a site depends on many site characteristics (e.g., mean grain size, percentage of fine-grained sediment, porosity and level of saturation) and on the regional geology, which influences the amplification and attenuation of strong-motion amplitude. Ground-motion modeling may help in defining a priori the liquefaction potential (e.g., Nunziata et al. 2008).

Strong-Ground Motion Modeling

Due to the destructive potential of earthquakes, a goal is to develop methodologies for modeling strong-ground motions from seismic sources related to active faults and subduction zones with high probability of earthquake occurrence. Confidence in such modeling relies on the theoretical part of strong-motion seismology and on the calibration of the techniques against the empirical data.

One of the most common methods to simulate broadband strong-ground motion is the use of records from small earthquakes occurred in the vicinity of the source area of a large earthquake. This kind of modeling of the strong motion is known as empirical Green's function method, and it has been proposed by Hartzell in 1978 and largely reviewed and applied through the years (see e.g., Irikura 1986; Dan et al. 1990). The empirical Green's function method has been applied in simulating strong-ground motions from a large event, even using observed records of just one or two small events. The records are used as the empirical Green's functions over the fault plane of the large event by correcting only attenuation effects due to difference in distance from each subfault to the site. The advantage of this approach relies in the fact that the seismograms contain all the complexities of wave propagation. On the other hand, the serious disadvantage is that the empirical Green's functions may not be available for the desired source-station path and may originate by an earthquake with a focal mechanism and/or depth different from the desired one.

Very recently, a procedure, called "recipe of strong-motion prediction," has been developed to the aim of obtaining ground-motion time histories from specific earthquakes (Irikura et al. 2004). Such a recipe is based on source characteristics obtained from the waveform inversion using strong-motion data. The idea is to follow a procedure, outlined as a recipe, for characterizing the source model estimating three kinds of source parameters: outer-, inner-, and extra-fault parameters. The outer are to outline the overall properties of the target earthquake, such as entire source area and seismic moment; the inner are parameters characterizing stress heterogeneity inside the fault area; the extra parameters are considered to complete the source model, such as the starting point and propagation pattern of the rupture.

The theoretical approach to the simulation of strong motion, based on the computation of synthetic seismograms,

has experienced an impressive growth in the last decades. A description of both analytical and numerical methods can be found, e.g., in Anderson (2003), Bolt and Abrahamson (2003), Bielak et al. (2003). Hybrid techniques, obtained combining analytical and numerical methods, e.g., modal summation method and finite difference (Panza et al. 2001), wave number method and finite difference (Zahradnik and Moczo 1996), finite element and boundary integral method (Bielak et al. 1991), have been developed and a review of these methods dating back to 1980 can be found in Moczo et al. (1997). Numerical-modeling methods for anelastic wave propagation, that take into consideration the earthquake source, propagation path, and local site effects, have become available for the estimation of the site responses and, more generally, for addressing the problem of solving the wave equation in 3D models. Then simulations based on finite difference (see e.g., Sato et al. 1998) or, more recently, finite element (see e.g., Bielak et al. 2003) and Spectral Element Method (SEM) (see e.g., Komatitsch and Tromp 2002a, b; Komatitsch et al. 2004) have been largely used in order to simulate strong-ground motion in 3D structures. A very recent development (La Mura et al. 2010) extended the very efficient analytical modal summation (Panza et al. 2001) to 3D anelastic structures.

Strong-Motion Simulation: An Example

In this section, an example of simulation of strong ground motion is discussed. The determination of the seismic ground motion due to an earthquake with a given magnitude and epicentral distance from the site has been done following a theoretical approach. In order to perform an accurate and realistic estimate of ground shaking scenario, it is necessary to make a parametric study that takes into account the complex combination of the source and propagation parameters, in realistic geological structures.

The realistic modeling of ground motion requires the simultaneous knowledge of the geotechnical, lithological, geophysical parameters, and topography of the medium on one side, and tectonic, historical, paleoseismological, seismotectonic models on the other, for the best possible definition of the probable seismic source.

To deal both with realistic source and structural models, including topographical features, a hybrid method, that combines modal summation and the finite difference technique (e.g., Panza et al. 2001) and optimizes the use of the advantages of both methods, has been used. Wave propagation is treated by means of the modal-summation technique from the source to the vicinity of the local, heterogeneous structure that has to be modeled in detail. A laterally homogeneous, anelastic structural model is adopted that represents the average crustal properties of the region. The generated wavefield is

Earthquakes, Strong-Ground Motion, Fig. 1 From bottom to top: local geotechnical model schematizing the surface geology along the Warth bridge. Black triangles show the sites of the abutments and of the piers along the section. Transverse acceleration time series computed at the eight pier sites. The amplitude of the signals is normalized with respect to the maximum one (0.4 g). Blue and red curves correspond to the case of forward and neutral directivity, respectively. Peak Ground Velocities (PGV) calculated along the profile, for forward (blue curves) and neutral (red curves) directivity, for a unilateral rupture and for the bedrock case (BED), that can be compared with the regression analysis for PGV made using a database of near-fault, forward-directivity

motions, proposed by: Somerville (1998) -SOM98- azure curve, Alavi and Krawinkler (2000) -AK00- orange curve and Rodriguez-Marek (2000) -RM00- green curve, for a magnitude equal to 5.5. Peak Ground Accelerations (PGA) calculated along the profile, for forward (blue curves) and neutral (red curves) directivity, for a unilateral rupture. Average Response Spectra Accelerations (ARSA) and ARSA + one standard deviation computed for the eight sites; blue and red curves correspond to the case of forward and neutral directivity, respectively. The black lines correspond to the two (Type 1 and 2) Design Spectra suggested by EC-8 (EN 1998) for a 5.5 magnitude earthquake and for a soil of class D

then introduced in the grid that defines the heterogeneous area and it is propagated according to the finite differences scheme. With this approach, source, path, and site effects are all taken into account simultaneously.

An example of seismic-input computation is illustrated. The computations are performed for the Warth bridge, freeway A2, 63 km south of Vienna (Austria), a location where no seismic records are available (see Romanelli et al. 2003, 2004). The information about the possible seismic input is limited to an estimate of the macroseismic intensity, in the range from VI to VIII (MSK), the value of the magnitude, M , of the nearest largest recorded event, $M = 5.5$ and the most probable focal depth of strong earthquakes, in the range from 6 to 11 km.

The synthetic time signals are calculated for the three components of motion and the working magnitude is 5.5 (seismic moment equal to 1.8×10^{17} Nm). The study of possible directivity effects in the direction of the Warth bridge (see cross section in Fig. 1) has been performed with the method developed by Gusev (2010), based on the modeling of a Haskell-type seismic source (Haskell 1964, 1966), where a stochastic component allows to build a spectrum (amplitude and phase) of the source function that takes into account both the rupture process and directivity effects. The near-source effect is shown in Fig. 1, where the acceleration time series at the eight sites are plotted in the case of forward (blue curves) and neutral (red curves) directivity for a unilateral rupture. In the figure are also reported the Peak Ground Velocities (PGV) and Peak Ground Accelerations (PGA) along the profile, for neutral (N) and forward (F) directivity, calculated for a unilateral rupture, both for the bedrock case and taking into account the local site conditions. The curves can be compared with the regression analysis for PGV made using a database of near-fault, forward-directivity motions proposed by Somerville (1998), Alavi and Krawinkler (2000) and Rodriguez-Marek (2000). From the results it is evident the strong influence of the rupture and site effects on the ground-motion characteristics, in terms of amplitude and duration. The accelerograms exhibit the greatest peaks in the frequency range, from 1 to 6 Hz, and reach considerable peak values, around 0.4 g.

The analysis of the computed strong-ground motion can be carried out in the time domain (broadband ground-motion time series) and other domains (e.g., Fourier and response spectra). The results show that lateral heterogeneities and source effects can produce strong spatial variations (e.g., more than doubling the amplitudes) in the ground motion (also in terms of differential motion) even over distances of a few tens of meters. In other words, considering that an increment of one intensity degree in the MCS scale roughly corresponds to a doubling of the PGA (Cancani 1904), a general result of the modeling is that a difference greater

than one unit in the seismic intensity can be experienced at sites as close as a few tens of meters.

Conclusions

Solution to earthquake engineering problems, either design or estimation of seismic hazard, are today very different than they were before a strong interaction between seismologists and engineers. Today the differences between strong motion and weak motion have been softened, due to progress in instrumentation and the awareness that both kinds of motions are useful to the understanding of the nature of earthquakes. Today it is unthinkable to study seismic-rupture processes and seismic-wave generation of large earthquakes without near-source strong-motion data; however, while waiting for the enlargement of the strong-motion data set, a very useful approach is the development and use of modeling tools based, on one hand, on the theoretical knowledge of the physics of the seismic source and of wave propagation and, on the other hand, exploiting the rich database about the geotechnical, geological, tectonic, seismotectonic, and historical information already available. With these efforts, the prediction of strong motions through physical modeling is adequate and desirable.

Earthquakes, Volcanogenic

J. W. Neuberg

Institute of Geophysics and Tectonics, School of Earth and Environment, University of Leeds, Leeds, UK

Definition

- | | |
|------------------------------|---|
| Volcano-tectonic earthquakes | “Conventional” double-couple earthquakes of shallow tectonic origin, occurring in a volcanic setting, and comprising primary (<i>P</i>) and secondary (<i>S</i>) waves as well as surface waves. |
| Rock-fall events | High-frequency (above 2 Hz), “cigar-shaped” signals caused by the surface impact of solid, crystallized lava dome material, consisting mainly of surface waves. |
| Low-frequency earthquakes | Earthquakes with low-frequency content (0.5–2 Hz), generated at the interface between a magmatic fluid and solid rock, causing parts of the volcanic plumbing system such as conduits, dykes, and cracks to resonate. |
| Volcanic tremor | Either unstructured, random background noise on a volcano caused by magma movement, or merging swarms of low-frequency earthquakes that retain all characteristics of the single events. |
| Very-long-period earthquakes | Seismic transients with periods between tens of seconds and several minutes, caused by magma/gas movement in the shallow plumbing system. |

Volcano Seismology

Introduction

Volcano seismicity covers a large variety of seismic signals caused by the complex interaction of magmatic and hydrothermal fluids with solid rock within the volcanic edifice leading to stress changes, brittle failure of rock, pressure variations, magma fracturing, and fragmentation. Volcano seismology has the aim to identify and separate different seismic signals and attribute them to physical processes, a task that helps volcanologists to understand the dynamics of the magmatic systems.

The interpretation of different volcanogenic seismic signals and the development of conceptual and numerical models are at the core of any attempt to forecast volcanic eruptions. While volcano seismology emerged from earthquake seismology, it has evolved into a separate discipline in its own right, dealing with a large complexity of seismic source processes in a volcanic environment.

Crucial for the interpretation of seismic signals is the examination of their frequency content by Fourier or frequency analysis by which the signal is decomposed into harmonic waves and contributions of single frequencies are compared with each other. This decomposition is called a frequency spectrum, and its repeated application in consecutive time windows is referred to as a spectrogram. It turns out that different volcanogenic signals can be easily identified and separated by their frequency content; hence, we will make frequent use of this methodology in the following sections where the characteristics and the possible origin and source mechanism of different volcanogenic signals are described. Single event types are classified according to their suspected

source mechanism rather than using a phenomenological classification relying on their waveform and frequency. A comparison of the three main types of volcanogenic signals and their respective frequency spectra are shown in Fig. 1, while volcanic tremor and very-long-period transients are depicted in Figs. 3, 4, and 5, respectively. An overview describing the development of seismic methods over the last decade using these volcanogenic signals can be found in Chouet and Matoza (2013).

Volcano-Tectonic Earthquakes

Volcanoes are often located in tectonically active areas such as subduction zones, where earthquakes are generated merely by changes in the regional stress field due to the continuous movement of the tectonic plates. When magmatic and hydrothermal processes occur at the same location and time, the local stress field is further modulated and impacted upon by these processes. It is this complex interaction between the regional stress field and local stress modulation by volcanic processes such as dyke intrusion and (de)pressurization of the

Earthquakes, Volcanogenic, Fig. 1 Different event types in time and frequency domain, recorded on Soufriere Hills volcano on Montserrat: (a) volcano-tectonic earthquake (VT), (b) low-frequency earthquake, and (c) rock-fall event

volcanic plumbing system that leads to the generation of volcano-tectonic earthquakes, referred to in the following as VTs for brevity. These stress changes can be created directly by magma emplacement, or indirectly by temperature changes or pressure changes as a result of magma–water interaction in a hydrothermal system.

Assuming that the pressure modulation through a magmatic body produces only a localized effect on the overall stress field impacting only on close distance of a few hundred meters from the magmatic source, the earthquake location in itself indicates the emplacement of fresh magma (or its withdrawal). Hence, the locations of VT earthquakes over a certain time period are an indicator of changes in the system rather than providing a picture of a so-called magma chamber. VTs are generated by *stress changes*, as a consequence of *magma movement*. In this way, Battaglia et al. (2005) traced the rising magma dyke through time at Piton de la Fournaise, La Reunion. White and McCausland (2016) used VTs to detect initial stress changes and the corresponding volumes of intruding magma and demonstrated the forecasting potential of VTs in several examples.

Being generated by brittle fracture of rocks along a fault plane, VTs have all the characteristics of local earthquakes: containing a clear primary (*P*) wave, followed by the secondary (*S*) wave, both in the frequency range of 1–20 Hz (see Fig. 1a). If the recordings of several seismic stations are available, the hypocenter of the event can be located using standard seismological tools, as well as other seismic source parameters, which can be obtained by the fault plane solution. Typical VTs range in magnitude *M_b* between 1 and 3.

Another major difference to usual tectonic earthquakes lies in the geometry of the fault plane. While tectonic events can be sufficiently modeled using piecewise straight fault planes, VTs might be generated on strongly curved fault planes in the volcanic plumbing system of dykes and conduits. This has significant implications on amplitude estimations and the determination of a so-called moment tensor that describes the interaction of forces in the source process. Some of the consequences can be an underestimation of amplitudes and a misinterpretation of the source time history (Contreras-Arratia and Neuberg 2019).

Rock-Fall and Lahar Events

This event type is produced by the impact of falling rock fragments on the surface of the volcanic edifice, and therefore, is typical for dome-building eruptions involving highly viscous magma. There is a continuum between small rock avalanches to highly energetic, so-called pyroclastic flows, which are a mixture of hot gas and rock fragments, ranging from huge boulders to fine volcanic ash particles. The impact that generates the seismic signal depends on rock size, impact angle, and the property of the surface.

The signal, a typical example of which is depicted in Fig. 1c, has a “cigar-shaped” waveform, increasing in amplitude as more and more rocks form a rock avalanche, gaining speed and momentum. Secondary phases can be identified in the waveform as the flow reaches a change in topography slope converting its kinetic energy into a seismic signal. The frequency content is very high, containing mostly surface waves. The end of the “cigar” is reached once the material involved in the flow has settled. Rock-fall signals occur sometimes as secondary events in connection with low-frequency events that are able to cause significant seismic shaking of a dome structure (see below) or volcanic explosions resulting in a shower of volcanic ejecta and collapsing eruption columns. Another signal with a similar waveform is caused by so-called *lahars*, high-density mudflows that can keep big boulders in suspension. These mudflows occur often after heavy rainfall or through melting icecaps that cover parts of the volcano. While rock-fall and lahar events do not offer a detailed insight into magmatic processes within the volcano, they can still be used as a proxy for magmatic extrusion rate, assuming that the lava disintegrates and falls off the dome at the same rate as it is extruded. A further use of lahar and rockfall events lies in the real-time monitoring and determination of the hazard and risk these phenomena might cause.

Low-Frequency Earthquakes

Low-frequency earthquakes, depicted in Fig. 1b and in the following referred to as LF, proved to be pivotal to modern volcano seismology. Several examples have been quoted where these events have been successfully used to forecast volcanic eruptions (e.g., Chouet 1996). Their occurrence alone has been used as an indicative tool even though a full understanding of their source mechanism had not been achieved. On Galeras volcano, Colombia, the occurrence of a few low-frequency earthquakes played a major role in the heated scientific and public debate regarding whether lives could have been saved had their occurrence been recognized as a warning sign for an imminent volcanic eruption (Gil Cruz and Chouet 1997).

Low-frequency earthquakes occupy a spectral range of approximately 0.2–10 Hz and form a spectral continuum between two end-members of seismic categories: *long-period events* and so-called *hybrid events*, which are similar to long-period events but carry in addition a high-frequency onset. On Soufriere Hills volcano in Montserrat, it has been demonstrated that the amount of high-frequency energy observed in the seismic signal can vary from station to station, and also at one station from event to event. Therefore, long-period and hybrid earthquakes have been grouped together under a more generic term as *low-frequency earthquakes* (Neuberg et al. 2000). These events have been observed on many, mostly dome-building volcanoes, and have been empirically

associated with the pressurization of the volcanic system (Lahr et al. 1994; Neuberg et al. 1998).

Very different from tectonic events, low-frequency earthquakes are generated at a boundary between a fluid, such as gas or magma contained in conduits, dykes, or cracks, and the solid surrounding rock (e.g., Ferrazzini and Aki 1987; Chouet 1988; Neuberg et al. 2000). Most of the seismic energy is trapped in the fluid-filled plumbing system – conduit, dyke, or crack – and resonates within this system while only a small part can escape and propagate through the volcanic edifice and is recorded at the surface. Hence, low-frequency earthquakes are generated by resonating interface waves – hence the term *conduit resonance* – however, these interface waves must not be confused with acoustic waves in the fluid, often referred to as organ pipe modes. Acoustic and interface waves differ in one important aspect: Interface waves are dispersive; hence, the velocity varies with wavelength, and it is the slow moving part of the wave field that explains the low-frequency character (Ferrazzini and Aki 1987). Figure 2 shows the

horizontal and vertical seismic component of a synthetic, resonating interface wave for a two-dimensional dyke model. The single overtones, or modes, are separated by frequency in the depth–frequency plot. The low-frequency seismic wave can be considered as the superposition of these modes. The frequency content is controlled by the interface wave velocity which, in turn, is determined by the rigidity μ of the surrounding rock, the bulk modulus of the fluid κ , the wavelength of the interface wave, and the width of the fluid-filled container.

Low-frequency earthquakes are observed on many volcanoes, and most observations include one or several of the following characteristics: (1) LFs occur in swarms, (2) the waveforms are very similar, (3) their occurrence is highly regular, (4) with increasing occurrence, the LF swarms merge into continuous tremor, and most importantly, (5) major dome collapses or other eruptive phases are preceded by LF swarms (Miller et al. 1998; Aspinall et al. 1998; Hellweg 2003). The highly periodic occurrence of LFs in

Earthquakes, Volcanogenic, Fig. 2 Eigen modes of a low-frequency earthquake source: spectral amplitude distribution for horizontal (X) and vertical (Z) component inside (above) and outside (below) the conduit for single frequencies. The superposition of the frequency contributions

represents the source signal inside the conduit and outside. Note that the vertical component is affected by the interaction with the free surface, while the horizontal component is not

swarms of similar waveform can be seismologically interpreted as a stationary seismic source with a repetitive non-destructible source mechanism (Green and Neuberg 2006). The other exciting aspect is their potential as a forecasting tool for volcanic eruptions or dome collapses. Both Galeras volcano in Colombia and Soufriere Hills volcano in Montserrat are examples where LF swarms occurred before such events; however, the occurrence of the earthquakes does not guarantee a volcanic event. This demonstrates that the mere occurrence of LFs is not yet a reliable forecasting tool unless the actual trigger mechanism is understood and a direct link between the seismogram and source mechanism can be made.

Several trigger mechanisms for LFs have been proposed, including magma–water interaction (Zimanowski 1998), stick-slip motion of magma plugs (Goto 1999; Iverson et al. 2006), magma flow instabilities (Julian 1994), periodic release of gas–ash mixtures into open cracks (Molina et al.

2004), and repeated, brittle fracturing of magma in glass-transition (Neuberg et al. 2006).

Volcanic Tremor

As indicated in the previous section, one definition of volcanic tremor is the superposition of low-frequency earthquakes as they merge in time. Figure 3 depicts an example in time and frequency domain from Soufriere Hills volcano in Montserrat where single LF earthquakes merge into tremor. If the highly periodic occurrence, or trigger mechanism, is maintained, the tremor signal exhibits a spectral signature of integer harmonic spectral lines (see Fig. 3) if the time window from which the spectral slice is computed is long enough to cover several events. The distance between the spectral lines is inversely related to the time separation between LFs of the same waveform, origin, and time history. As the frequency of occurrence increases, the distance between spectral lines will increase as well. In this way, one can measure the inter-event time, or

Earthquakes, Volcanogenic, Fig. 3 Seismic low-frequency earthquake swarms merging into tremor: spectrogram (upper part) and seismogram (lower part). Note the *lines* in the spectrogram toward the end of

the signal, representing a highly periodic repeated excitation of identical events. The spectral distance between the lines corresponds to the excitation frequency

event rate, by using the separation of spectral lines, even though the single events have merged in time into a continuous tremor signal. For this type of volcanic tremor, it has been shown that the spectral signature of the tremor signal is identical to the low-frequency earthquakes of which it is composed (Latter 1981).

Another definition of volcanic tremor is more general and refers to the background noise caused by magmatic processes.

Figure 4 shows an example from Piton de la Fournaise, La Reunion, where volcanic tremor is produced by lava extruding from fissures. The onset and end of the tremor signal are remarkably sharp and coincide with the start and finish of the eruption. The spectrum of the signal is “white”; hence, it is composed of a large number of frequencies and does not have any spectral structure. The origin of the tremor is due to pressure fluctuations during turbulent magma flow (Julian

Earthquakes, Volcanogenic, Fig. 4 Spectrograms of continuous tremor at Piton de la Fournaise, La Reunion. (a) Onset of tremor is preceded by a short swarm of VT events, (b) continuous tremor during

lava extrusion, note the extremely sharp end of the tremor signal when magma extrusion stops

1994). Another tremor source of this kind can be attributed to hydrothermal activity or degassing. While such a tremor signal does not have any distinct seismic phases (like *P* and *S* wave arrival) that could be used to determine the source location on the base of relative travel times, the relative amplitudes of the signal can be utilized to obtain an approximate location of the tremor source as demonstrated by Taisne et al. (2011).

Very-Long-Period Earthquakes

With the availability of broadband seismic sensors, seismology opened a new window to very-long-period signals caused by transients of pressure variations in the volcanic edifice with periods ranging from tens of seconds to several minutes (Neuberg et al. 1994; Wielandt and Forbriger 1999). Measurements in this frequency range close the gap between classic seismology and ground deformation as determined by strain-, tilt-meters, and GPS. However, while ground deformation can be measured directly as ground *displacement*, a seismometer detects the ground *velocity*, or the temporal change of the displacement, due to its electromagnetic measurement principle, reacting to the *change* of the magnetic flux by inducing an electric current. The advantage of such a system lies in the high sensitivity of the detection system; the disadvantage is that several data processing steps are necessary to retrieve the ground displacement, if this is the quantity required for modeling or further interpretation. For short-period signals, this does not pose any problem as the instrument response is constant in this narrow (high-) frequency band; hence, the seismogram has only to be integrated to convert ground velocity into displacement. However, for a broadband seismometer, the instrument response is highly frequency dependent and lower frequencies are suppressed by the seismometer. In order to retrieve the ground displacement from the measured ground velocity, the effect of the instrument response has to be taken into account and, if possible, to be removed. This is in addition to the integration step in the data processing sequence.

Modern broadband seismometers have a “flat” frequency response typically in the range between 50 and 0.008 Hz, expressed in periods, between 0.02 and 120 s. Figure 5 shows the effect of the removal of the instrument response in an example from Stromboli volcano. The seismic record of a Strombolian eruption shows an ultra-long-period transient in the vertical direction, caused by an ascending magma/gas plug with an eruptive, high-frequency seismic signature superimposed. In order to represent the long-period part of the signal properly, the original velocity seismogram has to be corrected for the instrument response as well as integrated. This processing sequence is shown in Fig. 5, where the velocity seismogram is converted to displacement by integration (Fig. 5a), and where finally, after the instrument response has been successfully removed, the seismogram (Fig. 5d)

Earthquakes, Volcanogenic, Fig. 5 Very-long-period signal from Stromboli volcano after removal of instrument response. (a) through (d) indicate the period limit to which the spectral energy has been included in the restitution. While the trace in (a) contains only spectral components up to 120 s period, the true ground displacement is reconstructed by including all spectral components to a period of 500 s (c) or even 1000 s (d). The final result in the lowermost trace shows the ground displacement associated with the rising gas slug, the Strombolian explosion as well as the deflation after the explosion

represents the true ground displacement at the location of the seismic sensor. The comparison between corrected and uncorrected displacement demonstrates the importance of this processing steps. An interpretation or model of the uncorrected trace (Fig. 5a) would comprise an upward movement of the volcanic edifice prior to the Strombolian eruption followed by a deflation and slow recovery of the edifice. The corrected trace offers a much simpler interpretation (Neuberg and Luckett 1996): The edifice inflates while the magma plug is ascending, and once the gas is released through the eruption the edifice deflates to its original level. This example demonstrates that each seismic sensor, and indeed each recording instrument, has to be considered a *filter* that affects and modifies the original physical signal in a certain way, often introducing a frequency-dependent change in amplitude and phase that results in an entirely different waveform. To correct for these effects is absolutely essential when very-long-period seismic signals are interpreted in terms of volcanic source processes.

Volcano Seismology in a Wider Volcanological Context

Volcanogenic earthquakes have been the first signals to be used to monitor and assess volcanic activity, and are today still at the core of any volcano monitoring program. However, if combined with other observations and integrated into wider conceptual and numerical volcanological models, their potential as a forecasting tool increases even further. In the following section, we give a few examples how volcanogenic earthquakes have been used to assess several aspects of volcanic activity.

Estimation of Magma Ascent Rate

A very exciting example from Montserrat has been reported by Voight et al. (1998), where a radial tilt signal recorded on Chances Peak, an old dome structure adjacent to the active lava dome of Soufriere Hills volcano, correlated perfectly with the cyclic occurrence of seismic swarms. Neuberg et al. (2006) reinvestigated this correlation and found that seismic activity, in this case, low-frequency earthquake swarms, commences when the tilt signal goes through an inflection point (Fig. 6). Furthermore, low-frequency seismicity ceases when the tilt signal goes through a second turning point. The tilt, which is the rotation of the volcano's flank, is caused by a combination of a pressure buildup in a shallow magma reservoir and the shear stress acting across the conduit wall by the motion of viscous magma at shallow depth (Green et al. 2006). Hence, the cyclic occurrence of LF swarms can be directly related to the magma ascent rate: As the pressure in the magma has reached a certain threshold, magma starts to move causing low-frequency seismicity by either a stick-slip motion (Iverson et al. 2006) or by magma rupture (Neuberg et al. 2006). This causes the turning point in the tilt behavior;

however, the ground deformation (tilt) still increases to its maximum where the magma ascent rate peaks. At this point, the magma ascent slows down as gas bubble diffusion cannot keep up with the pressure drop, caused by the magma movement. This can be clearly seen in both the tilt signal and the seismicity rate depicted in the inset of Fig. 6. At the second turning point, magma ascent rate has become so low or even stopped completely that no further LF seismicity is produced. This gives gas diffusion a chance to catch up, leading to a renewed pressurization of the system again, and a new cycle has started.

Tungurahua volcano in Ecuador shows a similar anti-correlated behavior of tilt and seismicity pointing to a mechanism where shear stress at the conduit wall is responsible for both the generation of LFs and tilt. Shear stress partitioning leads to the anticorrelation where tilt decreases when shear stress is released by slip through the generation of earthquakes (Neuberg et al. 2018).

These examples demonstrate how LF seismicity can be interpreted following a conceptual model that allows to estimate the changes in magma ascent rates on the base of seismicity, even if no tilt signal is available. Using such a model, Hammer and Neuberg (2009) found an accelerating seismicity rate in consecutive LF swarms on Montserrat – as a proxy for an accelerated magma ascent – which led to a dome collapse in 1997.

Combining Seismicity with Infrasonic Signals

A second example of a combined interpretation uses infrasonic acoustic signals with seismicity. The monitoring of infrasonic signals on active volcanoes has become routine in the last 10 years and turned out extremely helpful for open volcanic systems.

Earthquakes, Volcanogenic, Fig. 6 Correlation between tilt and seismicity on Soufriere Hills volcano, Montserrat. The low-frequency seismicity is sorted in different event “families.” The different colors indicate different families of similar seismic waveform which implies that each family has a common source mechanism and origin. It commences and ceases at the inflection points of the tilt signal (solid line), equivalent to the maximum and minimum of its time derivative (dotted line)

See Johnson (2003) for an overview on infrasonic monitoring techniques. Compared to seismic waves, infrasonic signals are less affected by the medium (steam and air) through which they propagate, and the relative timing between the two types of signals can be used to dissect a complex volcanic event such as a dome collapse, which can last for several hours and exhibit distinct phases. Green and Neuberg (2005) modeled a partial dome collapse at Montserrat in 2004 and used the relative timing between seismic and infrasonic pulses to separate several distinct explosions during the collapse. Furthermore, they identified a plume forming degassing event as the underlying cause of the collapse. A further application of a combined interpretation can be found in Ripepe et al. (2002) where relative timing between infrasound and seismic signal revealed the relative height of a magma column on Stromboli volcano from where an explosion occurred.

Detection of Lahars and Pyroclastic Flows

Pyroclastic flows, lava flows, and lahars often escape direct visual observation, but the fast determination of their location can be crucial in terms of risk mitigation. As pointed out above, the seismic signals produced by such events lack any clear seismic phase that could be used for a classic travel-time-based location procedure. Jolly et al. (2002) devised a method based on a relative seismic amplitude estimation across a seismic monitoring network, which allowed to follow the path of a flow in near real-time. The basic idea is to determine the location of the seismic surface source by assuming that the amplitudes of the surface waves caused by the flow decay by the inverse of the distance to a seismic station and by inelastic attenuation. They performed a so-called grid search inversion across the volcanic edifice to locate the flow. Through this technique, they were able to resolve fine details of the flow propagation such as a “piling-effect” that occurred when the front of the pyroclastic flow came to a halt while the rest of the flow piled up behind it, causing the seismic source traveling up hill!

On Piton de la Fournaise, a similar method is used (Taisne et al. 2011) to detect the source of basaltic lava flows, which are responsible for the generation of a tremor signal. In this way, the observatory staff is able to inform the authorities in near real-time about the source location of the lava flow.

Detecting Stress Changes in Volcanic Settings

Recent advances have made it possible to detect temporal variations in properties of seismic signals that are caused by stress changes in the medium that they penetrate. These changes can be seen in directional variations of the wave speed (also referred to as anisotropy), energy loss, and seismic source parameters (fault plane solution) of volcano-tectonic events.

Gerst and Savage (2004) detected a change in anisotropy at Mt Ruapehu, New Zealand, which coincided with the

eruptive activity in 1995 and 1996. They interpreted these changes to be caused by changes in the stress due to magmatic activity that altered the orientation and volume of cracks in the volcanic edifice. Using noise correlation techniques, Brenguier et al. (2008) observed at Piton de la Fournaise, La Reunion, similar changes in seismic velocity caused by the pressurization of the volcanic edifice due to ascending magma. Roman et al. (2006) found systematic variations in the orientation of the main pressure axis, which was derived from fault plane solutions of volcano-tectonic events on Soufriere Hills volcano on Montserrat. They identified distinct episodes in the eruptive history of Soufriere Hills volcano, where the regional stress field was superimposed by local stress perturbations that caused the pressure axis determined from VT fault plane solutions to swing around by 90°. Again, these stress changes were interpreted as caused by ascending magma, and indeed, these episodes preceded in some cases the restart of dome growth and magma extrusion. While the methods mentioned in this section do not necessarily utilize only volcanogenic earthquakes, they employ seismological tools to monitor the stress perturbations caused by volcanic activity, and therefore, could lead to new methods of volcanic forecasting.

Summary and Conclusions

Monitoring and interpretation of volcanogenic earthquakes are core tasks of any volcano observatory. The separation into different event types allows us to attribute seismic activity to certain volcanic processes. While some event types are directly caused by brittle failure during magma ascent, or by extrusion of magma at the surface, other seismic signals provide us with indirect evidence of changes caused by the volcanic-magmatic system. Volcano seismology emerged from classic earthquake seismology as a separate discipline focusing on the special character of seismo-volcanic source processes. This development is ongoing, and classic seismic techniques such as the determination of seismic moment tensors will be applied in the future to the wider variety of seismo-volcanic sources which can be significantly different from usual earthquake sources acting on a single fault plane. With the availability of seismic broadband sensors, volcano seismology overlaps with high-frequency acoustic emissions on one side of the seismic spectrum and with deformation signals on the low-frequency end. Multidisciplinary approaches combining seismology with other signals recorded on volcanoes will lead to more detailed insights into volcanic processes.

The use of *machine learning* and *artificial intelligence* will allow us to jointly interpret increasing amounts of data in volcano observatories leading to improved risk assessment and mitigation.

Electrical Properties of Rocks

Takashi Yoshino

Institute for Planetary Materials, Okayama University,
Misasa, Japan

Definition

Electrical conduction	The movement of electron or electrically charged particles through a medium.
Electrolyte	Any substance containing free ions that make the substance electrically conductive. The most typical electrolyte is an ionic solution.
Fermi level	The highest energy of occupied states in a solid at 0 K. The Fermi level in conductors lies in the conduction band, in insulators it lies in the valence band, and in semiconductors it falls in the gap between the conduction band and the valence band.
Stern layer	One of the two electrically charged layers of electrolyte ions: the layer of ions immediately adjacent to the surface and the layer in the neighborhood of a negatively charged surface.

Introduction

The interpretation of electromagnetic data obtained from the electromagnetic (EM) induction method requires knowledge of electrical properties of rocks comprising the Earth's interior. The electrical properties of rock are now widely used in electrical conductivity (resistivity) and induced polarization to identify zones of ore deposits and to probe the thermal and compositional structure in the Earth's interior. For example, electrical resistivity measurements have been firstly used in 1960s to prospect the sulfide ore deposits. Electrical conductivity of the crust and mantle by the electromagnetic (EM) induction method represents an important contribution to our knowledge of processes in the Earth's interior independently of the seismological studies, because the electrical conductivity is sensitive to small amounts of accessory phases such as fluid, melt and metal in rocks, and small amounts of hydrogen and ferric iron in rock-forming minerals.

The bulk electrical properties of rocks contain complex combination of various electrical processes consisting of solids (silicates, oxides, and metal), pores filled with air or liquid, and interfaces between solid and liquid, because rocks are composites of wide variety of minerals occasionally containing fluid and melt. Since 1960s, many studies of electrical properties in rocks and rock-forming minerals have been performed as functions of frequency, temperature,

pressure, oxygen fugacity, water content, applied electric field and other variables. Recent development of analytical technique and an improvement of resolution for the electromagnetic observations has led to an increase of interest in the electrical properties of rocks at depth within the Earth. At such depths, pressures and temperatures are very high, and laboratory studies in which these pressures and temperatures can be realized have been needed to predict the electrical properties at high pressures corresponding to the depth of the Earth's interior. Within the last two decades, many efforts were concentrated on the measurement of high-pressure phases to obtain knowledge of temperature, composition, and water content in the Earth's interior. As a result, the maximum range of pressure where the electric conductance can be measured currently covers the pressure condition of the core-mantle boundary (2900 km depth).

Definition of Electrical Conductivity (Resistivity)

When an electric potential V is applied across a material, electric current (I) in a material is proportional to the voltage across it according to Ohm's law: $V = IR$, where R is the electrical resistance, which depends on the intrinsic resistivity ρ of the material and on the geometry (length l and area A through which the current passes).

$$R = \frac{\rho l}{A}$$

The electrical conductivity (σ) is the inverse of the resistivity. The current density (J) can be expressed as $J = E/\rho = E\sigma$. The conductivity is one of the properties of materials that varies most widely, from 10^7 (S/m) typical of metals to 10^{-20} (S/m) for good electrical insulators. Semiconductors have conductivities in the range 10^{-6} – 10^4 (S/m).

Electrical Conduction

An electrolytic process can be considered as a dominant mechanism for electron charge transport in shallower crustal rocks developing pores and cracks that filled with fluid electrolytes. At high saturation conditions, conducting currents in electrolyte primarily arise from the flow of ions in electric field. The conductivity of an electrolyte is controlled by solute concentration, ionic charge, and other physical parameters such as temperature and pressure. Fluid saturated rocks contain interface between mineral and fluid. Surface conductivity can be considered as an additional electrical conductivity of fluid in the vicinity of the charged surface. Concentration of ions becomes higher close to the charged surfaces because of attractive electrostatic forces induced by the surface

charge. This layer with high concentration is called as the electrochemical double layer (DL) composed of Stern layer in contact with solid and diffusive layer in contact with fluid. Higher concentration of ions in the Stern layer leads to higher conductivity. The significant influence of surface conductivity on bulk electrical properties appears for porous samples saturated with dilute electrolytes and low porous samples where the thickness of the DL is the same order as crack width. A mixed conduction process of electrolyte and surface conductivity is most likely at low saturation conditions.

As pressure and temperature increase, electrical conduction in rock-forming mineral is likely to control the bulk electrical conductivity of rocks by reduction of open space and interface effect in rocks. Solids can be classified in terms of their conductivity as conductors, semiconductors, or insulators. The classifications of solid materials can be visualized in terms of the band theory and are strongly correlated with the interatomic spacing in the solid. The electron energy levels in a solid are often expressed in relation to the Fermi energy. In metals, the electrons occupy states up to the Fermi level. Conduction occurs by promoting electrons into the conduction band that starts at the Fermi level. The promotion energy is negligibly small so that at any temperature electrons can be found in the conduction band. The number of electrons participating in electrical conduction is extremely small. In semiconductors and insulators, the valence band is filled, and no more electrons can be added, following Pauli's principle. In insulators, there is a large energy gap between the valence and conduction bands, so huge energy is needed to promote an electron to the conduction band. Semiconductors can be divided into intrinsic or extrinsic. Intrinsic conduction means that electrical conductivity does not depend on impurities, thus intrinsic means pure. In extrinsic semiconductors, the conductivity depends on the concentration of impurities. Electronic conduction occurs by electrons and electron holes. The electrical conductivity of semiconductors can be enhanced by doping to produce *n* (negative)-type or *p* (positive)-type semiconductors.

Silicates and oxides are usually insulator at ordinary temperature. Since the large energy gap of insulator could be overcome by heat, the silicate minerals can behave as a semiconductor at high temperatures corresponding to conditions of the Earth's interior. Mobility of lattice defects and a small amount of impurity such as hydrogen, ferric iron, and so on enhances electrical conduction of silicate minerals at high temperatures. The conductivity of ionic-bonded crystals is proportional to number and mobility of charge carriers. It is known from the Nernst-Einstein equation that electrical conductivity (σ) depends on the number (N) of electric charge carriers per unit volume;

$$\sigma = Nze\mu$$

where z is the charge number, e is the charge of electron, and μ is mobility.

The dependence of conductivity on temperature is like other thermally activated processes:

$$\sigma = A \exp(-\Delta H/2kT)$$

where A is a pre-exponential constant, ΔH is an activation enthalpy, k is the Boltzmann constant, and T is absolute temperature. Plotting log normal σ vs. reciprocal temperature ($1/T$) produces a straight line of slope $\Delta H/2k$ from which the band gap energy can be determined. Extrinsic semiconductors have, in addition to this dependence, dependence due to the thermal promotion of electrons from donor levels or holes from acceptor levels. The dependence on temperature is also exponential but it eventually saturates at high temperatures where all the donors are emptied or all the acceptors are filled. This means that at low temperatures, extrinsic semiconductors have larger conductivity than intrinsic semiconductors. At high temperatures, both the impurity levels and valence electrons are ionized, but since the impurities are very low in number and they are exhausted, eventually the behavior is dominated by the intrinsic type of conductivity. The activation enthalpy (ΔH) can be also defined as a function of pressure (P) as follows: $\Delta H = \Delta E + P\Delta V$, where ΔE is the activation energy and ΔV is the activation volume.

Ionic (intrinsic) conduction can occur at high temperatures through the creation of cation vacancies. In the ferromagnesian mantle minerals (silicates and oxides), the charge carriers are generally vacancies in magnesium site. The activation enthalpy of ionic conduction is usually higher than 2 eV. For this reason, extremely high temperatures are needed to observe the ionic conduction. Proton conduction is a kind of ion conduction. Because the proton is overwhelmingly small ion but massive compared with electron, the proton is the only ion which is expected to be highly mobile in solids. The energy barrier for the transportation of charge carriers for proton conduction is relatively low because of its small bonding energy and small ionic radius. The activation enthalpy of proton conduction is usually less than 1 eV and tends to decrease with increasing a number of hydrogen in minerals at very low concentrations. The proton conduction is a dominant conduction mechanism at low temperatures, whereas it has been known that the presence of hydrogen in crystal structure can occasionally enhance the ionic conduction.

The most dominant conduction mechanism for the ferromagnesian minerals such as olivine is hopping (small polaron) conduction. Hopping conduction occurs through charge transfer between neighboring ions of different valence. A ferrous ion (Fe^{2+}) generally substitutes an Mg ion in an Mg site. However, a certain proportion of ferric ion, which has an electron hole, exists dependent on oxygen fugacity, temperature, pressure, and crystal structure. Transfer of an electron hole between ferrous and ferric iron sites carries an electric charge, which is the hopping conduction. If only electron holes migrate in crystal, the energy barriers for the migration

would be low. However, presence of an electric hole significantly affects the local structure of the ionic crystal. A presence of ferric iron generates an extra positive charge, which repulses cations and attracts anions. This complex of the local strains is called “small polaron.” The migration of electron holes associates that of the small polaron. The relatively large activation enthalpy is needed to move a small polaron. The hopping conduction of usual ferromagnesian silicates has relatively large activation enthalpy (>1 eV). Activation energy for hopping conduction decreases with increasing iron concentration. The conductivity of ferromagnesian minerals is also controlled by the oxidation state of iron. A variation of the oxygen fugacity from an oxidizing to a reducing environment decreases the conductivity, due to the reduction of Fe^{3+} to Fe^{2+} . At the same oxygen buffer, the conductivity tends to increase with increasing iron content in minerals.

Electrical Conductivity of Liquid-Bearing Rocks

The effective conductivity of liquid-bearing rocks is very sensitive to the pore geometry in rocks. The enormous contrast in conductivity between silicates and liquids implies that electrical currents will flow almost totally through the pore liquid within rocks. Archie (1942) proposed an empirical equation that relates the bulk conductivity of σ_r to the conductivity of a pore saturating fluid σ_f . The rocks were assumed to exhibit interconnected porosity, and no disturbance due to the presence of reactive minerals was considered. The ratio σ_f/σ_r is known as the formation factor, F . Archie's law forms the basis for resistivity log interpretation:

$$F = \frac{\sigma_f}{\sigma_r} = C\phi^{-n},$$

where C and n are constants. Archie's law is not a geometrical model. There are various theoretical models for estimating the bulk conductivity of liquid-bearing rocks from the conductivity of liquid and solid phases. A frequently used model to predict the maximum effective bulk conductivity of an interconnected two-phase mixture is Hashin and Shtrikman (HS) upper bound (Hashin and Shtrikman 1963). This upper bound is representative for liquid phases distributed along grain boundaries and filling triple junctions of spherical grains. The opposite case representing the isolated spheres of liquids in solid grains is known as the HS lower bound.

Electrical Conductivity of Crust

The shallower zone of the upper crust consists of a sequence of sedimentary rocks along with fractured crystalline rocks. Because these rocks contain pores and cracks that are filled

with fluid electrolytes, they are moderately good conductors of electricity. As well as electrolyte conductivity, surface conductivity caused by electrochemical reactions between the fluid electrolyte and the mineral surface contribute additionally to the bulk conductivity. This zone has conductivities varying from about $10^{-0.5}$ S/m in recent sediments to 10^{-3} S/m or more in weathered crystalline rock. As pressure increases, the rock conductivity decreases due to the reduction of porosity. Remarkable changes in electrical properties often occur at mid-crustal depth, probably caused by the development of incipient fractures. If the fractures are filled with fluid electrolytes, electrical conductivity would largely enhance compared to the surrounding dry crystalline rocks. Secular changes in electrical conductivity might be used in predicting earthquakes.

The lower crustal rocks mainly consist of crystalline igneous or metamorphic rocks which are thought to be much more dense, having little pore space in which water may collect. Since the main rock-forming minerals are highly insulating at crustal temperatures, electrical conductivity in such rocks should be expected to be lower values than the upper crust. However, magnetotelluric (MT) and deep geomagnetic soundings (GDS) have revealed an unexpected high conductivity anomaly in the lower crust. A very small portion of well conducting material may cause enhanced conductivity of the whole rock mass provided that material fills interconnected pore space or covers grain surfaces. To generate the conductive layer, an indispensable interconnectivity of the well conducting phase must be established and maintained over large distances under deep crustal conditions.

Geophysicists traditionally considered aqueous fluids as the likely origin (Shankland and Ander 1983), because in active tectonic environments, aqueous fluid can supply via metamorphic dehydration, igneous activity, and introduction of fluids derived from dehydration of subducting plate. Figure 1 shows conductivity-temperature curves of conductivity layers in crust compared with conductivity measurement results of fluid-bearing rocks. Laboratory conductivity measurements suggest that the electrical conductivity of the aqueous fluid-bearing quartzite was found to be more than a few orders of magnitude higher than that of dry crustal rocks, but the conductivity is definitely lower than the observed values of the high-conductivity anomalies. The conductivity of the brine-bearing quartzite increases with salinity and fluid fraction, but slightly increases with increasing temperature. Unlike brine-free system, the small decrease of the conductivity with temperature is quite consistent with the temperature dependence of the specific conductivity for NaCl solution. Crustal rocks with fluid of high salinity (>10 wt%) is needed to account for the high conductive regions with the conductivity of 10^{-1} S/m. There is a small negative dependence of bulk conductivity on aqueous fluid fraction. Because the mobility of dissolved ions has little temperature dependence, the bulk conductivity maintains high values even at low temperatures.

On the other hand, in stable cratons fluids would be gravitationally driven but would be able to gain access only to the upper 10 km or so of the crust. Below this depth, the crust would be “dry.” The discovery of grain-boundary films on minerals in high-grade rocks (Frost et al. 1989) has led to a very reasonable alternative to aqueous fluids as a cause of conductivity anomalies. Duba and Shankland (1982) used the upper bound formula to calculate the absolute amount of well-ordered graphite required to enhance the conductivity of dry rocks. They found that a volume fraction of carbon of only $5 \times 10^{-6}\%$ could cause a conductivity of 0.1 S/m if well interconnected. However, high wetting angles of CO_2 – quartz system cannot establish along grain boundaries to form a connecting graphite film upon reduction of CO_2 . In addition, graphite films on the grain boundary of silicate minerals are readily destroyed by high interfacial energy (Yoshino and Noritake 2011). The origin of high conductivity anomalies observed in the lower crust where aqueous fluid is absent is still an unsolved problem.

Electrical Conductivity of the Earth’s Mantle

Electrical conductivity of mantle rocks tend to be similar to that of the most dominant phase, unless small amounts of conductive phase establish interconnection. Conductivity generally increases with increasing depth to the top of the

lower mantle, from 10^{-3} – 10^{-2} to 10^0 S/m. This increase is considered to be the semiconductive behavior of the constituent minerals at high temperatures because mantle temperature adiabatically increases with depth, and by pressure-induced phase transformations of dominant mantle minerals. Figure 2 shows the electrical conductivity of the main constituent mantle minerals in the Arrhenius plot. The mantle minerals with higher-pressure stability field tend to have higher conductivity in order of olivine, wadsleyite, ringwoodite, bridgmanite, and post-perovskite. A phase transformation affects electrical properties due to a change in the atomic arrangement (crystal structure), as well as the nature of chemical bonding. The phase transitions would yield the conductivity jumps at some certain depths where seismic velocity suddenly changes. Thus, the electrical conductivity measurements of the main mantle minerals to depths of up to the core-mantle boundary indicate that the Earth’s mantle is zoned electrically. This tendency can explain the geophysically observed electrical conductivity structure in the mantle well. In the lower mantle, there is no phase transition down to the D” seismic discontinuity. Because activation enthalpy for small polaron and ionic conduction is smaller for mantle minerals with higher-pressure stability field, as pressure increases, temperature dependence becomes smaller. For this reason, a uniform electrical conductivity is expected to exist in the lower mantle. On the other hand, the D” layer composed of post-perovskite might be an abnormally high

Electrical Properties of Rocks, Fig. 1 Field conductivity-temperature curves of crust (solid lines) compared with laboratory measurement of conductivity in “dry” granite and “wet” granite with 1–2% water (modified after Shankland and Ander 1983). Also shown are laboratory measurements of conductivity in fluid-bearing crustal rocks (Shimojuku et al. 2014; Guo et al. 2015)

Electrical Properties of Rocks, Fig. 2 Electrical conductivity of mantle minerals with $\text{Mg\#} = 90$; olivine, wadsleyite, ringwoodite, bridgmanite, ferro-periclase ($\text{Mg\#} = 83$), and post-perovskite in Arrhenius plot modified after Yoshino (2010)

conductive layer. Thus there should be huge conductivity jump at the D'' discontinuity.

Origin of High Conductive Anomalies in the Mantle

High-conductivity anomalies in the mantle have been observed and predicted in various depths and would be caused by thermal anomaly, relatively high concentrations of water, and iron in mantle minerals or a presence of fluid or partial melt. The current understandings of their conductivity anomalies are summarized here.

Oceanic Asthenosphere

The high conductive layer with anisotropic signature at the top of the asthenosphere (60–100 km depth) was observed near the Eastern Pacific Rise and cannot be explained by the conductivity characteristics of ordinary anhydrous olivine (Evans et al. 2005). One possibility is that partial melting occurs in the region and the melt forms an anisotropic, interconnected conductive path in the partially molten peridotites. Another possibility is that olivine in the region contains considerable amounts of hydrogen inside crystal structures, and thus electrical conductivity is substantially elevated by proton conduction (Karato 1990). Wang et al. (2006) reported large effect of water on electrical conductivity of olivine, and concluded that 10^{-2} wt.% water is enough to explain high conductivity anomaly of oceanic asthenosphere. On the other hand, Yoshino et al. (2006) reported that the electrical conductivity of single crystal hydrous olivine is nearly isotropic and distinctly lower than the observed conductivity. The majority of subsequent studies did not support the contribution of hydrous olivine to the conductivity. Thus hydration of olivine cannot account for the geophysical observations, which instead may be explained by the presence of partial melt with basaltic composition elongated in the direction of plate motion. The experimental results demonstrate that alignment of 2 vol% of the melt in peridotite causes conductivity anisotropy by one order of magnitude higher in the direction parallel to the shear compared with normal to the shear on the shear plane (Zhang et al. 2014). The expected melt fraction in the regions where conductivity anisotropy is observed is only up to 0.2 vol%. Because electrical conductivities of hydrous and carbonate melts are more than a few orders of magnitude higher than those of hydrated olivine, high conductivities in the asthenosphere may be explained by the presence of very small amounts of hydrous carbonate melt in peridotite (Gaillard et al. 2008; Sifré et al. 2014). However, recent studies have pointed out that the effect of temperature dependence on the electrical conductivity of hydrous olivine becomes larger at higher temperatures because of a change of conduction mechanism in hydrous olivine. The debate on whether the origin of the conductivity anomaly is water or melt has continued.

Mantle Transition Zone

The Earth's mantle transition zone (410–660 km depth) has been considered as a large water storage area because wadsleyite and ringwoodite, which are high-pressure polymorphs of olivine, can enter significant amounts of water in their crystal structures. If these phases are dry, their conductivity values are too low to explain the conductivity-depth profiles in the transition zone obtained by the semi-global electromagnetic induction studies. Therefore, effect of water on electrical conductivity was investigated to determine the water content in this zone. Water content on electrical conductivity of their minerals was estimated to be 0.1 wt.% from the average conductivity profile in the mantle transition zone (Yoshino and Katsura 2013). On the other hand, the conductivity anomalies observed in the mantle wedge require high water content over the solubility limit. Such high conductivity values suggest the presence of supercritical fluids in this region, leading to a persistence of local water saturation and continuous release of supercritical fluids at the stagnant slab roof on geological time scales. This phenomenon can account for both the high-conductivity and seismic-velocity anomalies observed in the mantle wedge at the transition-zone depth.

The Base of the Lower Mantle

Perturbations in the Earth's rotation rate at decadal time-periods require the existence of dissipative coupling at the CMB, leading to the presence of a thin conductive layer with a conductance of 10^8 S or greater. Several models have been proposed to explain anomalously high electrical conductance in some regions above the CMB: (1) capillary rise of iron-rich melt into the mantle; (2) a suction mechanism for iron entrainment into the mantle; (3) penetration of molten iron into the mantle by morphological instability; (4) presence of post-perovskite or extremely Fe-rich (Mg,Fe)O with high electrical conductivity. The first three requires at least a 200-m thick metallic solid layer at the top of the core. The conductivity data of post-perovskite showed extremely high conductivity ($>10^2$ S/m) in comparison with that of bridgmanite, and little temperature dependence at the conditions of D'' layer (Ohta et al. 2008). A ~300-km-thick post-perovskite layer provides an alternative explanation.

Conclusions

The electrical conductivity of rocks within the Earth shows an ultimate variation that exceeds eight orders of magnitude. The electrical conductivity measurements of rocks as a function of temperature, pressure, oxygen fugacity, and impurity concentrations can constrain thermal and compositional structure in the solid Earth. At shallower depths, electrolytes filled with cracks or grain boundaries control the conductivity of rocks,

whereas the conductivity of the mantle rocks is mainly controlled by semiconductive behavior of the constituent minerals. In the last two decades, development of measurement techniques for electrical properties of rocks and minerals under high-pressure and high-temperature conditions has improved our understanding of the electrical structure of the Earth's deep interior up to the core-mantle boundary. Although some discrepancies of data among laboratories have remained due to the difficulty of the electrical conductivity measurement at high pressures, it is not doubtful that the Earth's mantle is electrically zoned, and the conductivity generally increases with depth. Further improvement of experimental techniques will provide us accurate reference conductivity-depth model up to depth of the core-mantle boundary and more detailed knowledge of chemical composition and thermal distribution in the present Earth's interior by comparison with the results of the electromagnetic surveys.

Definition

Electrical survey – Mapping the subsurface resistivity by injecting an electric current into the ground

Electrode – Commonly a metal rod through which the current is injected into the ground or is used to measure the induced voltage on the ground surface

Least-squares resistivity inversion – Finding the subsurface resistivity model that minimizes the sum of squares of the differences between the measured and calculated apparent resistivity values

Introduction

Electrical resistivity surveys map the subsurface structures by making electrical measurements near the ground surface. An electric current is injected into the ground through two

electrodes, and the voltage difference is measured between two other electrodes (Fig. 1a). The true subsurface resistivity can be estimated by making the measurements of potential difference at different positions of the current and potential electrodes, converting these values into apparent resistivity and then inverting the data set. The ground resistivity is related to various geological parameters such as the mineral and fluid content, porosity, and degree of water saturation in the rock (*electrical properties of rocks*). Over the past 25 years, the resistivity method has undergone rapid developments in instrumentation, field survey techniques, data interpretation, and novel applications in the geosciences. It has now become one of the standard geophysical exploration techniques widely used in environmental, engineering, hydrogeological, and mining investigations (Loke et al. 2013).

The basic data from a resistivity survey are the positions of the current and potential electrodes, the current (I) injected into the ground, and the resulting voltage difference (ΔV) measured between the potential electrodes (Fig. 1a). The current and voltage measurements are then converted into apparent resistivity (*instrumentation, electrical resistivity*), ρ_a , by using the following formula:

$$\rho_a = k \frac{\Delta V}{I}, \quad (1)$$

where k is the geometric factor that depends on the configuration of the current and potential electrodes (Koefoed 1979).

Over the years, various electrode configurations (or arrays) have been developed. Figure 1 shows the arrangements for some commonly used arrays. A discussion on the merits of the different arrays is given by Dahlin and Zhou (2004), Szalai and Szarka (2008), and Martorana et al. (2017). There has also been substantial work in nontraditional arrays that maximize resolution of the subsurface (Wilkinson et al. 2012) or maximize the use of unused channels on multi-channel resistivity meters (Cubbage et al. 2017). Determining the true subsurface resistivity from the apparent resistivity values is the data inversion problem.

Traditional Profiling and Sounding Surveys

The resistivity survey method has its origin in the 1910s due to the work of the Schlumberger brothers. Traditionally resistivity surveys were divided into profiling and sounding surveys. The distances between the electrodes are kept fixed in a profiling survey, and the four electrodes are moved along the survey line. The data interpretation for profiling surveys was mainly qualitative. The second type of survey is the vertical sounding method (usually with the Schlumberger array) where the center point of the electrode array remains fixed, but the spacing between the electrodes is increased to obtain deeper subsurface information. Apparent resistivity plotted as a function of the current electrode spacing gives information on subsurface resistivity variations (Fig. 2a).

Electrical Resistivity Surveys and Data Interpretation, Fig. 1 Common arrays used in resistivity surveys and their geometric factors. The current is injected into the ground through the C1 and C2 electrodes, while the voltage difference is measured between the P1 and

P2 electrodes. For the arrays with fewer than four electrodes, the remaining electrodes are placed at sufficiently large distances so that they do not affect the measurements

Electrical Resistivity Surveys and Data Interpretation,

Fig. 2 Example of (a) 1-D sounding curve and (b) layered earth model

Quantitative data interpretation for sounding surveys uses a one-dimensional (1-D) earth model with a series of horizontal layers (Fig. 2b). One commonly used method for 1-D data inversion is the iterative damped least-squares method (*inverse theory, linear*) (Marquardt 1963; Inman 1975; Koefoed 1979) that is based on the following equation:

$$[\mathbf{J}_i^T \mathbf{J}_i + \lambda_i^2 \mathbf{I}] \Delta \mathbf{q}_i = \mathbf{J}_i^T \mathbf{g}_i, \quad (2)$$

where the data misfit vector $\Delta \mathbf{g}$ contains the difference between the logarithms of the measured and the calculated apparent resistivity values and $\Delta \mathbf{q}$ is a vector consisting of the deviation of the estimated model parameters from the true model. Here, the model parameters are the logarithms of the resistivity and thickness of the model layers. $\mathbf{J}$ is the Jacobian matrix of partial derivatives of apparent resistivity with respect to the model parameters. λ is a regularization factor that stabilizes the ill-conditioned Jacobian matrix usually encountered for geophysical problems (*inverse theory, singular value decomposition*). i represents the iteration number. Starting from an initial model (such as a homogeneous earth model), this method iteratively refines the model so as to reduce the data misfit (Fig. 2a) to a desired level. A detailed description on the use of the iterative damped least-squares method for the inversion of resistivity sounding data is given by Inman (1975).

The resistivity sounding method has been used for many years, particularly in groundwater exploration. The greatest limitation of this method is that it does not take into account lateral changes in the subsurface resistivity which can result in errors in the interpreted resistivity and thicknesses of the layers. A two-dimensional (2-D) survey and interpretation model is required for more accurate results.

Two-Dimensional Resistivity Imaging Surveys

Since the early 1990s, development of multielectrode resistivity meter system (*instrumentation, electrical resistivity*)

has made 2-D surveys a practical tool for mapping moderately complex geological environments. The apparent resistivity measurements from the survey are commonly plotted in the form of a pseudosection (Loke et al. 2013). The pseudosection (Fig. 3a) is a useful method to present the data in a pictorial form, but it gives a distorted picture of the subsurface because the shapes of the contours depend on the type of array used as well as the true subsurface resistivity.

A 2-D model that consists of a large number of cells is commonly used to interpret the data (Loke et al. 2013). The finite-difference (*numerical method, finite difference*) or finite-element methods (*numerical method, finite element*) are used to calculate the apparent resistivity values for the 2-D model. A nonlinear optimization method is then used to automatically change the resistivity of the model cells, so as to reduce the data misfit. Smoothness or other constraints are usually incorporated to stabilize the inversion procedure such that numerical artifacts are avoided. As an example, the following equation includes a model smoothness constraint to the least-squares optimization method:

$$[\mathbf{J}_i^T \mathbf{R}_d \mathbf{J}_i + \lambda_i^2 \mathbf{W}^T \mathbf{R}_m \mathbf{W}] \Delta \mathbf{q}_i = \mathbf{J}_i^T \mathbf{R}_d \mathbf{g}_i - \lambda_i^2 \mathbf{W}^T \mathbf{R}_m \mathbf{W} \mathbf{q}_{i-1}. \quad (3)$$

$\mathbf{W}$ includes the roughness filters in the x-, y-, and z-directions (deGroot-Hedlin and Constable 1990). $\mathbf{R}_d$ and $\mathbf{R}_m$ are weighting matrices employed if the L1-norm inversion method is used (Farquharson and Oldenburg 1998). A number of computer software packages are now available that can automatically carry out the inversion of a 2-D survey data set in seconds.

Figure 3a shows an example of a measured apparent resistivity pseudosection from a survey using the dipole-dipole array. The resistivity model after inversion is shown in Fig. 3b. This survey was part of a long-term landslide monitoring program. From the base to the top of the slope, the formations are the Lias Group Redcar Mudstone Formation (RMF), Staithes Sandstone and Cleveland Ironstone

Formation (SSF), and Whitby Mudstone Formation (WMF). Slope failure occurs within the WMF in the upper parts of the slope (Uhlemann et al. 2017).

Three-Dimensional Resistivity Imaging Surveys

Since all geological structures tend to be three-dimensional (3-D) in nature, a 3-D resistivity survey and interpretation model (Fig. 4) should give the most accurate results. Although it has not reached the same level of usage as 2-D surveys, it is now more widely used in very complex areas such as in environmental and mineral exploration surveys (Loke et al. 2013). Many of the early 3-D surveys used the pole-pole array over relatively small grids (up to about 20 by 20 electrodes) with measurements in different directions (Loke and Barker 1996). The use of other arrays, such as the pole-dipole and Wenner-Schlumberger, is now becoming more common in 3-D surveys that involve thousands of electrode positions (Loke et al. 2013). Ideally, the electrodes should be arranged in a rectangular grid to get a full 3-D coverage. However, a more cost-effective strategy is usually followed wherein 3-D data sets are collated from independent 2-D survey lines. This strategy greatly reduces the cost of a 3-D survey and also allows for 2-D inversions of each individual line. The data interpretation techniques used for 2-D surveys can be extended to 3-D surveys (Loke and Barker 1996). Fast computer software that takes minutes to hours to

invert a 3-D data set (depending on size) on multicore PCs are now available. Other nonlinear optimization methods such as neural networks, simulated annealing, and conjugate gradient techniques have also been used for resistivity data inversion (Pellerin and Wannamaker 2005).

Figure 4 shows an example from the Hanford site in Washington state, USA, where liquid waste of high ionic strength (mostly comprised of sodium nitrate) was disposed in trenches and concrete cribs (Rucker et al. 2009). Different resistivity survey phases were carried out using 2-D lines in different directions and spacings. The linear high resistivity features near the surface are due to the trenches and concrete cribs. The leakage zones are marked by the prominent low resistivity zones in the deeper regions.

The field survey and data inversion methods have been adapted for other types of problems such induced polarization (IP) surveys (Fiandaca et al. 2013), measurements across boreholes (Wilkinson et al. 2008), aquatic surveys (Rucker and Noonan 2013; Dahlin and Loke 2018), cylindrical geometries (Chambers et al. 2004), measurements with long electrodes (Rucker et al. 2010), and mobile survey systems (*instrumentation, electrical resistivity*).

4-D Time-Lapse Surveys

In time-lapse surveys, measurements using the same array configurations are repeated, usually at regular intervals, to

Electrical Resistivity Surveys and Data Interpretation, Fig. 4 A 3-D survey (electrodes marked by black dots) and model. Blue regions have resistivity of less than 100 ohm.m, while light-green and orange regions have resistivity above 400 ohm.m

monitor temporal changes in the subsurface resistivity. The least-squares optimization method can be modified for time-lapse surveys, so as to minimize temporal changes in the model resistivity values (Kim et al. 2009; Loke et al. 2014), as shown by the following equation:

$$\begin{aligned} & [\mathbf{J}_i^T \mathbf{R}_d \mathbf{J}_i + (\lambda_i^2 \mathbf{W}^T \mathbf{R}_m \mathbf{W} + \alpha_i^2 \mathbf{M}^T \mathbf{R}_t \mathbf{M})] \Delta \mathbf{q}_i \\ &= \mathbf{J}_i^T \mathbf{R}_d \mathbf{g}_i - (\lambda_i^2 \mathbf{W}^T \mathbf{R}_m \mathbf{W} + \alpha_i^2 \mathbf{M}^T \mathbf{R}_t \mathbf{M}) \mathbf{q}_{i-1}. \end{aligned} \quad (4)$$

$\mathbf{M}$ is a difference matrix (with regularization factor α) applied across the time models to minimize the difference in the resistivity of each model cell and the corresponding cell for the next temporal model. The data misfit vector $\mathbf{g}$ now incorporates the measurements from all the time-series data sets, while the model vector $\mathbf{q}$ incorporates the resistivity values from all the temporal models (Kim et al. 2009).

Sophisticated integrated monitoring data acquisition systems have been developed in recent years (Uhlemann et al. 2017; Poje et al. 2018) that can automatically carry out the measurements at preset times and transmit the data over the Internet to a processing center where it is automatically

inverted. Figure 5 shows an example from a survey to monitor the flow of a leaching reagent through a rock ore heap as part of a secondary recovery method at a gold mine (Poje et al. 2018). Plots of the change in saturation (calculated from the change in the resistivity) show the regions within the rock heap penetrated by the leaching reagent. The volumes of the regions covered by the plumes provided an estimate of the value of the gold and silver extracted using the known concentration of the metals.

Summary

The electrical resistivity survey method has undergone tremendous changes over the past 25 years. While traditional resistivity profiling and sounding surveys are still used, 2-D imaging surveys are now the method of choice for most areas as they can accurately map moderately complex structures. The field equipment and computer interpretation software are widely available. 3-D surveys now play an increasingly important role in very complex areas. In many cases the 3-D data set is collated from a number of separate 2-D survey

Electrical Resistivity Surveys and Data Interpretation, Fig. 5 Stacked plumes of 5% saturation increase for different zones from injects at wells W1 and W2 (a) side view and (b) overhead view

lines. There have been rapid developments within the past decade in the instrumentation, data acquisition techniques, and inverse modeling techniques for 4-D time-lapse surveys to monitor temporal changes in the subsurface resistivity.

Electromagnetic Methods, Imaging Magma Bodies

Kathryn A. Whaler

School of GeoSciences, University of Edinburgh, Edinburgh, UK

Definition: Essential Concepts

Electromagnetic (EM) methods probe the electrical resistivity, or its inverse, electrical conductivity, of the subsurface. The magnetotelluric (MT) method depends on time-dependent naturally occurring magnetic fields external to the Earth inducing eddy currents in the subsurface whose strength and geometry depend on the subsurface resistivity distribution. These decaying currents generate magnetic fields, and by monitoring changes in both the electric and magnetic fields at the surface, information about the subsurface resistivity can be inferred. More slowly varying magnetic fields penetrate deeper, so separating the signals into their frequency components allows depth resolution of the resistivity structure. Penetration depth also depends on the subsurface resistivity. It is characterized by the “skin depth,” $\delta \approx 500\sqrt{\rho T}$, which, in a uniform Earth of resistivity ρ (Ωm), is the depth (in m) at which a signal of period T (in s) is attenuated to $1/e$ of its surface amplitude. Lightning discharges (sferics) trapped in the ionospheric waveguide and interactions between the magnetosphere and solar wind provide the signal at short and long periods respectively. Between the two, centered on about 1 s period, lies the reduced power “dead band.”

The electric and magnetic fields are measured in (or resolved into) two orthogonal horizontal directions, and the MT data are often supplemented by measurements of the vertical magnetic field. Other than on ice-covered surfaces, electric fields are deduced from the potential difference between two (nonpolarizing) electrodes, typically separated by around 100 m. The magnetic field is measured by induction coils – many turns of fine wire around a metallic core – at shorter periods (up to 10,000 s or so), and fluxgate magnetometers for longer periods. The measured field variations are very small, so it is important to install equipment carefully and minimize noise. Electrode separation must be measured accurately, and the electrode lines, and induction coils or magnetometers must be orientated, and the induction coils or magnetometer components leveled, precisely. Equipment is buried to reduce wind noise, wherever possible away from trees. Moving people, equipment, and vehicles generate noise, and electrical infrastructure (e.g., power lines, generators, electric fences) is especially problematic, although notch filters at the appropriate frequency and its harmonics can help. Typically, practitioners aim to locate sites at least 500 m from “cultural” noise. This limits the locations at which MT data acquisition is possible. Depending on the noise levels, depth of interest and typical resistivities of the study area, data will be recorded for half a day up to several months, with 1–3 days being typical in magmatic regions where the crust and uppermost mantle are of primary interest.

Small-scale structure in the shallow subsurface generates galvanic (noninductive) effects that distort the MT signals. Controlled source transient electromagnetic (TEM), also known as time-domain EM (TDEM), methods can be used to infer the shallow structure and correct for this galvanic distortion if the resistivity structure is one- or two-dimensional. In three-dimensions, joint inversion with MT data is undertaken. TEM/TDEM involves injecting a current pulse into a wire loop laid onto the surface and measuring its decay and the induced magnetic field at the loop’s center.

Sea water effects distort – even dominate – data from sites near the coast. “Near” is indicated by the skin depth – longer periods can be affected even if the coastline is many tens of kilometers away. This can be a significant problem when attempting to use MT to study volcanic islands, although corrections can be calculated from bathymetry models.

Controlled source EM (CSEM) methods are also used, particularly in the marine environment. They overcome loss of power in the dead band, and the source power can be increased where necessary to improve signal-to-noise. However, the processing and modeling of CSEM data is more complicated – in passive MT, the signal is treated as a “harmonic plane wave from infinity,” whereas the source geometry and distance from the receivers must be accounted for in CSEM.

MT data are processed in the frequency domain using robust methods to estimate and then manipulate the

so-called impedance tensor or transfer function, a 2×2 tensor whose four elements are the ratio of the electric to magnetic field components in the two orthogonal horizontal directions. If data are recorded synchronously at a second, less noisy site, remote reference methods can be used to improve the impedance tensor. These four (complex) numbers can be expressed in terms of their amplitude and phase; with a suitable scaling, the amplitude has units of resistivity and is referred to as apparent resistivity, and the phase is the lag between the magnetic and electric fields. The structure of the impedance tensor indicates the dimensionality required to explain the data. Over a uniform medium, the diagonal elements of the impedance tensor vanish and the two off-diagonal elements are equal; the apparent resistivity is the actual resistivity of the medium, and the phase is 45° . The diagonal elements also vanish if the resistivity structure is one- or two-dimensional, in the latter case only so long as the data are rotated into the geoelectric strike direction (i.e., the direction along which structure does not vary). Rotation to find the optimum geoelectric strike direction can be coupled with accounting for galvanic distortion; this is normally applied simultaneously to all sites at all periods intended for two-dimensional modeling. Phase data are unaffected by galvanic distortion, so some practitioners prefer to interpret only the phase information, which can be described by a quantity known as the phase tensor. The data are normally viewed as $\log(\text{apparent resistivity})$ and phase (or various properties of the phase tensor components) as a function of $\log(\text{period})$ (or $\log(\text{frequency})$) on a site-by-site basis, known as data curves, or else for a number of sites as a pseudo-section, with $\log(\text{period})$ acting as the depth proxy. Both types of plot help visualize the main features of the subsurface resistivity structure. For example, apparent resistivity decreasing or phase increasing with period indicates resistivity decreasing with depth. Galvanic distortion results in a vertical shift of apparent resistivity curves, and uncorrected data will place structure at the wrong depth. When the vertical magnetic field is also measured, the ratio of vertical to each horizontal component of the magnetic field (also estimated robustly in the frequency domain) form a vector known as the tipper. In the absence of lateral resistivity variations, the vertical field vanishes; thus, lateral variations “tip” the magnetic field out of the horizontal plane. Tippers are normally displayed as induction vectors whose real components point away from (in the Wiese convention) subsurface conductors. However, they are also affected by steep topography often associated with volcanoes. Thus, dimensionality analysis (and geoelectrical strike determination, in the two-dimensional case) is based on the structure of the impedance tensor, accounting for noise and galvanic distortion, and the tipper values.

The relationship between MT data and subsurface resistivity is strongly nonlinear, meaning inversion is fundamentally non-unique, as well as suffering from the usual ambiguities

associated with insufficient, inconsistent, and noisy data. Most practical algorithms minimize a combination of misfit to the data and a measure of model roughness (e.g., Constable et al. 1987). This, and the inherent diffusive propagation of the signal, tends to smear structure, although MT data resolve the top surfaces of conductors well. Their lower surfaces are considerably harder to image, even without issues of model regularization and data resolution, as currents will not penetrate deep into a conductor. Sensitivity analysis, to ascertain which model features are required to fit the data, can help, for example, by testing whether the conductor can be confined to a certain depth range. These tests rely on identifying systematic mismatches between data and their model predictions as much as an overall root-mean-square misfit.

The highly nonlinear nature of the MT inverse problem means inversion is computationally intensive, especially as the need to match boundary conditions “at infinity” means the model area or volume must be much larger than that covered by the data, and include a number of air layers above the Earth’s surface. There are guidelines for determining the appropriate model area/volume and the dimensions of model cells within it. Both isotropic and anisotropic inversion codes are used; data obtained over a two-dimensional anisotropic subsurface can be distinguished from those obtained over a three-dimensional isotropic subsurface by site-to-site consistency in the phase (Simpson and Bahr 2005). It is possible to introduce extra parameters accounting for galvanic distortion into inversion, for example, if TEM data are unavailable (e.g., Kelbert et al. 2014). A number of implementations of well-established algorithms are available for community use, both for data processing and subsurface resistivity modeling. Useful reviews of all aspects of the MT method can be found in the books of Simpson and Bahr (2005) and Chave and Jones (2012). Its application to magmatic systems is reviewed by Magee et al. (2018).

Observations

Fluids, including magma and partial melt, are generally considerably less resistive than solid rock, making them ideal for detection by EM induction methods that are particularly sensitive to conductive material. The signal propagates diffusively and hence it is inherently larger scale (particularly at depth) than seismic methods involving wave propagation. On the other hand, fluids and higher temperatures lower seismic wavespeeds, attenuate the signals, and thus make melt regions harder to image seismically. Thus, EM induction methods, especially MT, have been used extensively to study magmatic systems, in both terrestrial and marine, and many different tectonic environments. Here, a few examples are mentioned to illustrate the type of information obtained and problems faced.

MT data have imaged several low resistivity features beneath the central Andes, interpreted as dykes and magma reservoirs associated with Volcán Uturuncu. A sensitivity test showed that the intermediate depth (2–12 km) dykes were required. Beneath Unzen volcano, Japan, it was inferred from the resistivity structure that a magma column ascended at 20 m/day until it interacted with a water saturated layer; this explained the temporal changes in eruptive styles of the volcano in 1990–1991. The top few kilometers of the resistivity structure beneath Merapi volcano, Indonesia, have been probed, using MT and TEM. Owing to cultural noise from the high population density, only short period MT data were reliable. Pronounced topography effects were separated from resistivity structure when modeling and interpreting induction vectors. Conductive structures were attributed to hot, saline fluids (i.e., a hydrothermal system) rather than partial melt, contributing to the debate as to whether there is a superficial magma reservoir beneath Merapi. Other studies of hydrothermal systems include Mount Fuji, and Meakandake volcanoes, Japan, using MT and Mount St Helens, USA, using CSEM. Mount St Helens has a localized, shallow conductor that extends downwards to join a deeper and more extensive mid-crustal conductor, interpreted as zones of partial melt of silicic magma that erupted in 1980. Beneath Tianchi volcano, on the Chinese-North Korean border, a mid-crustal conductor, inferred to be a magma chamber, was imaged at a time of precursors of a possible eruption (earthquake activity and an increase in spring and surface water temperature). MT is also frequently used to explore high enthalpy geothermal systems, for example, in Iceland and the East African rift valley.

Monitoring of magmatic systems has been undertaken by both time-lapse and continuous EM measurement. Usu volcano, Japan, has been active since the seventeenth century and erupted in 1977–1978. A later MT study found that an initially conductive zone corresponding to the magmatic intrusion associated with the eruption had become resistive, indicating cooling from 800 °C to 50 °C. Impedance tensor changes on timescales of months at Sakurajima volcano, Japan, were ascribed to degassing. Continuous monitoring at La Fournaise, Réunion Island, recorded apparent resistivity decreases associated with the large 1998 eruption and changes to the phase tensor that were attributed to the injection of a N-S striking dyke. At quiet sites, it is possible that hydrologically related seasonal geothermal changes could also be monitored with MT.

MT data from Mount Vesuvius illustrate problems that can arise with galvanic distortion. Data curves from two studies had similar shapes, but the apparent resistivities corrected for galvanic distortion using TDEM were two log units lower. Interpretation of the uncorrected data was of a deep (~8–10 km) magma reservoir, whereas the corrected data suggest that there is a shallow brine layer and no deep

reservoir. The longer period data in both cases were affected by pervasive noise from DC electrified railways.

Marine EM studies have focused on mid-ocean ridges. At the fast-spreading East Pacific Rise, a ~10 km wide sub-vertical conductor slightly displaced from the ridge axis, connected to a deep, broad conductive zone, was interpreted to be a channel efficiently transporting melt to the base of the crust. From MT and CSEM, melt supply to crustal magma chambers beneath the slow-spreading Reykjanes ridge in the Atlantic Ocean appears to be intermittent and rapid. However, the extension of the slow-spreading Red Sea rift on land in Afar, Ethiopia, is underlain by a conductor inferred to contain voluminous melt, implying it is a persistent feature.

Interpretation

How can magma volumes be determined from EM studies? Bulk electrical resistivity is sensitive to melt distribution as well as the presence of electrically conductive fluid phases such as water. For instance, well-connected melt gives a lower bulk resistivity than isolated melt pockets, for the same melt fraction and resistivity. Two-phase mixing laws (e.g., Schmeling 1986) predict bulk resistivity from melt resistivity and geometry in the rock matrix. Resistivities of basaltic and rhyolitic melts have been measured in laboratory experiments (e.g., Laumonier et al. 2015; Guo et al. 2016), but are significantly altered by relatively modest changes in temperature, pressure, silica, sodium, and water content. Even if eruptive products have been well characterized, they may not reflect the current subsurface magma/partial melt composition. Crystallization within a magma reservoir can alter melt composition. These uncertainties make direct inference of melt fraction difficult. Nonetheless, information from laboratory studies, petrology, and geochemistry is always an aid to interpretation; see the review by Pommier (2014).

Other geophysical observations are usefully combined with resistivity information in the study of magmatic systems. For example, seismic data have corroborated the association of low resistivity anomalies with melt. The inference of ~4% connected melt at 10 km depth beneath the Taupo Volcanic Zone, New Zealand, was supported by low Vs values from receiver function studies; this was just beneath the brittle-ductile transition as indicated by the base of the seismogenic zone. Earthquake locations, along with Vp values, were used to infer repeat magma injection along a fault intersection near St George's Hill volcanic center, Montserrat. MT indicating extensive melt beneath an active Quaternary magmatic segment in Afar, Ethiopia, was supported by low Pn and surface wave velocities, high Vp/Vs values, and low amplitude receiver functions. Crustal conductors along the northern flanks of the main Ethiopian rift coincide with locations where receiver functions either have amplitudes too low to

interpret or indicate high V_p/V_s values. MT data indicate that earthquakes occurring deeper than the brittle-ductile transition in the main Ethiopian rift, but away from the Quaternary magmatic segments, are magma induced. They are focused where the lower crust is being modified by magma emplacement driven by partial melting of the upper mantle. MT results also indicate lower crustal magmatic underplating supplied by upper mantle melt at the Great basin – Colorado plateau transition in the USA; the inference is supported by seismic anisotropy (shear wave splitting) information.

Electrical anisotropy can also be inferred directly from two-dimensional MT data – the amount by the phase difference between the off-diagonal impedance tensor components, and the direction by the geoelectrical strike. There is moderate agreement between the direction and amount of seismic and electrical anisotropy beneath Quaternary magmatic segments in Afar, Ethiopia, where oriented melt pockets were proposed as the cause of large seismic anisotropy in the lower crust. Schmeling (1985, 1986) predicts bulk seismic wave speeds and electrical resistivity as a function of melt arrangement (tubes, disks, etc.), orientation (e.g., horizontal or vertical), and amount; joint analysis might enable a more robust interpretation of magma distribution. Gravity models of profiles across the main Ethiopian rift and an inactive Quaternary magmatic segment in Afar, Ethiopia, suggest partial melt coincident with low resistivity anomalies.

Sometimes resistivity evidence is difficult to reconcile with other information. The depth to the Antiplano-Puna magmatic body (APMB) in Bolivia is 3–8 km greater from MT than seismic receiver function and ambient noise tomography methods, although the slowest velocities are at the conductor's surface. There is a resistive body beneath Aluto volcano, Ethiopia, where other data including deformation, degassing, and seismic indicated a magma reservoir – in fact, the magmatic region below the superficial hydro-geothermal system is significantly more resistive than the surrounding region. Here, V_p values are low, suggesting a gaseous melt that could therefore have poor connectivity and hence high resistivity. A geochemical study suggests that Aluto's magmatic system is normally dominated by crystalline mushes containing ephemeral, small ($< 1 \text{ km}^3$) segregations of melt, another plausible explanation of its low resistivity.

Sensitivity tests can also aid in resistivity model interpretation. For example, beneath a rifting region of Afar, Ethiopia, models show a large conductor extending into the upper mantle, where melt should be too buoyant to reside. Confining the conductor to the crust significantly increased the overall data misfit, systematically misfitting the longer period data, and made crustal resistivity unfeasibly low. It was inferred to have a conductance (vertically integrated conductivity) of at least 10 kS, a value reasonably robust to its thickness – a similar conductance is obtained by decreasing the resistivity and the thickness of the conductor while

maintaining the data fit. The APMB in Bolivia has a conductance exceeding 20 kS and is at least 6 km thick. To put these values into context, 1 km of seawater has a conductance of about 5 kS.

Uncertainties in inferred magma volumes associated with the inability of MT to resolve melt distribution have been investigated. Geochemical evidence suggests melt in the mantle-straddling conductor beneath Afar should be in vertical stacks of sills, not a single large body as in regularized inversion models. Constrained inversion in which the conductor was divided up into horizontal layers of alternating resistive (solid rock) and conductive (sills containing partial melt) material provided an equally good fit to the data. The conducting layers had a much lower resistivity than when the conductive material was in a single large body, but the total melt volume in the two models was broadly similar. Hence, it is possible that geologically unrealistic MT models can nevertheless be used to infer magma volumes.

Conclusions

EM methods are becoming a standard tool to investigate and monitor magmatic systems. Developments in data acquisition, processing, and modeling, alongside laboratory investigations of the resistivity of melt over a range of compositions and conditions, have greatly increased their utility over the last few decades. The most robust interpretations are obtained when multiple data sets are combined.

Definition

Electromagnetic Pulsations	Short period geomagnetic field fluctuations in the range of 0.2 to 600 s.
Magnetic Storms	Large scale global disturbances in the geomagnetic field that last for about half a day to several days.
Magnetospheric substorms	Magnetospheric disturbances, resulting from an enhanced coupling between the solar wind and the geomagnetic field, that follow a set pattern lasting for a period ~ half an hour to a few hours.

Electromagnetic Pulsations

Variations in the Earth's magnetic field occur from hundreds of thousands of years to a fraction of a second. It is believed that the long period variations, from hundreds of thousands to tens of years, are caused by the geodynamo processes. On the other hand, the solar output is thought to drive, either directly or indirectly, the geomagnetic field variations at shorter periods varying from about 22 years to a fraction of a second. The geomagnetic field fluctuations at the shortest periods,

ranging from about ~0.2 to 600 s, are called electromagnetic pulsations or simply magnetic pulsations. Therefore, magnetic pulsations have frequencies that fall in the range of ultra-low-frequency (ULF: ~0 to 30 Hz) electromagnetic waves. The amplitudes of the electromagnetic pulsations are found to increase as their time periods increase (or their frequencies decrease). The amplitudes of the magnetic pulsations vary over a large range, from several hundreds of nT at the longest time periods (~600 s) to fractions of a nT at the shortest time periods (~0.2 s). On the ground, the magnetic pulsations are detected by magnetometers whereas in the magnetosphere, they are recorded by magnetic and electric field sensors onboard spacecraft.

Classification of Magnetic Pulsations

Depending on the waveforms and periods, the magnetic pulsations observed on ground can be classified into two broad types. The International Association of Geomagnetism and Aeronomy (IAGA) has formally done such a classification (Jacobs et al. 1964). Magnetic pulsations with quasi-sinusoidal waveforms are called pulsation continuous (Pc) whereas those with irregular waveforms are called pulsation irregular (Pi). Each main class is further subdivided into period bands that roughly characterize a particular type of pulsation as shown in Table 1.

It should be noted that during periods of disturbed geomagnetic activity, such as substorms and magnetic storms, giant magnetic pulsations, called Pc6 or Ps6, are observed with periods ranging from ~600–900 s. Recently, the seasonal and solar cycle modulation of the occurrence and characteristics of Pc3 pulsations at low latitudes has been discussed by Villante et al. (2019).

Generation Mechanisms of Magnetic Pulsations

Several plasma processes occurring in the solar wind and in the Earth's magnetosphere are responsible for the magnetic pulsations that are observed on the ground or in near-Earth space (McPherron 2005).

The Earth's magnetosphere is formed by the interaction of solar wind plasma coming out from the Sun and the geomagnetic field. This interaction leads to the geomagnetic field getting confined in a region of space around the Earth, which is known as the magnetosphere. Figure 1 gives a schematic of the three-dimensional view of the magnetosphere. It shows various important plasma regions as well as the current systems existing in the magnetosphere and at its boundary. Several plasma waves and instabilities are driven by the fluctuations in these magnetospheric currents as well as by the nonthermal distributions existing in the magnetosphere. Hence, variations in solar wind parameters can

Electromagnetic Pulsations and Magnetic Storms, Table 1 Classification of Magnetic Pulsations

	Continuous pulsations					Irregular pulsations	
	Pc 1	Pc 2	Pc 3	Pc 4	Pc 5	Pi 1	Pi 2
Period range (seconds)	0.2–5	5–10	10–45	45–150	150–600	1–40	40–150
Frequency range (mHz)	200–5000	100–200	22–100	7–22	2–7	25–1000	7–25

Electromagnetic Pulsations and Magnetic Storms,

Fig. 1 Schematic three-dimensional view of the earth’s magnetosphere formed by the interaction of solar wind from the Sun (from the left) with the geomagnetic field. Small arrows indicate the direction of the magnetic field lines. Thick arrows show the direction of electric currents. Various current systems present in the magnetosphere are shown

produce dramatic effects on the type of waves observed at a particular location at Earth.

Observations show that continuous pulsations having the same frequency range may have different characteristics, for example, their polarization, harmonic structure, or spatial location may not be the same. This suggests that there can be different generation mechanisms for Pc pulsations. In the literature, there are two popular mechanisms for the long-period (Pc3 to Pc5) magnetic pulsations. The first mechanism is based on field-line resonance theory where a monochromatic surface wave is excited by some plasma instability (e.g., Kelvin-Helmholtz (Kivelson and Pu 1984), drift mirror mode (Hasegawa 1969), etc.) at the magnetopause. This instability resonantly couples with a shear Alfvén wave associated with local field line oscillations (Chen and Hasegawa 1974). The second mechanism is based on cavity modes where global fast modes are excited throughout the entire magnetospheric cavity in response to sudden impulses in the solar wind (Kivelson and Southwood 1985). The cavity modes couple to field line resonances that drive currents in the ionosphere producing magnetic pulsations. However, some daytime Pc3 to Pc5 pulsations are believed to be driven directly by the solar

wind pressure fluctuations (Kepko et al. 2002). On the other hand, short-period continuous pulsations (Pc1 and 2) are thought to be excited by an electromagnetic ion cyclotron instability in the equatorial region of the magnetosphere. This instability is driven by the temperature anisotropy of the energetic protons either from the ring current or the plasma sheet region (Cornwall 1965). The irregular magnetic pulsations (Pis) are believed to be generated mainly by the coupling of global cavity modes to field-line resonances (Cheng et al. 1998). Nighttime Pi2 pulsations are most likely generated by earthward propagating fast mode waves launched at substorm onset by large-scale magnetic reconfiguration associated with cross-tail current disruptions (Baumjohann and Glassmeier 1984; Keiling and Takahashi 2011).

Substorms and Magnetic Storms

Substorms and magnetic storms are geomagnetic activity phenomena. A substorm (Akasofu 1964) consists of a set pattern of evolution of ionospheric auroral forms and magnetospheric disturbances lasting typically for about ~30 min to

E

an hour or so. Generally, many substorms occur in a day. During substorms, energy stored in the magnetotail is released explosively directed towards the inner magnetosphere in the midnight sector. This leads to the excitation of discrete auroras which become intense, widespread, and much more agitated than normal. Further, the field-aligned currents and the auroral (ionospheric) electrojets are intensified which produce disturbances in the geomagnetic field. The solar wind is the ultimate source of energy for substorms.

Magnetic storms (Gonzalez et al. 1994) are driven directly by solar drivers like interplanetary coronal mass ejections (ICMEs) and flares, and Corotating Interaction Regions (CIRs) associated with solar wind high speed streams (HSSs) emanating from coronal holes (Tsurutani et al. 1995, 2006). Magnetic storms occur during long intervals of intense southward interplanetary magnetic fields which considerably enhance the magnetic reconnection process (Dungey 1961). This leads to strong plasma injection from the magnetotail towards the inner magnetosphere causing intense global auroras at high and mid-latitudes, and at the same time intensifying the ring current which produces a diamagnetic decrease in the Earth's magnetic field measured at near-equatorial magnetic stations. This latter effect is the *main phase* of the magnetic storm.

Some magnetic storms are characterized by a sudden increase in the ground horizontal magnetic field intensity

shortly before the main phase [see top panel of Fig. 2]. These are known as the *sudden commencement* (SC) storms or *sudden impulse* (SI^+) prior to the storms. This sudden increase in the horizontal component of geomagnetic field is due to the compression of the magnetosphere by the interplanetary shock and downstream compressed plasma. The interval between the sudden commencement and the storm main phase used to be known as the storm *initial phase* but now is not considered to be part of the magnetic storm (Joselyn and Tsurutani 1990). However, all magnetic storms do not have an initial phase. On the other hand, a magnetic storm not accompanied by a SI^+ is called a *gradual geomagnetic storm* (SG) type [bottom panel of Fig. 2]. The *main phase* of a magnetic storm is caused by intensification of the ring current energetic ions injected into the inner magnetosphere ($L \sim 2-7$). During the main phase, the horizontal components of the low-latitude ground magnetic fields are significantly depressed over a time span of one to a few hours. After the ring current particle injection ends or starts to subside, and the ring current particle losses dominate input, the storm *recovery phase* begins. The recovery phase may extend for ~ 10 h or more. The intensity of a geomagnetic storm is measured in terms of the disturbance storm time index (Dst) or SYM-H (SYM-H is basically the same as Dst except the higher time resolution) index. The amount of magnetic field decrease is a measure of the total kinetic energy of the ring current particles (Dessler and Parker 1959).

Electromagnetic Pulsations and Magnetic Storms,

Fig. 2 Schematics of a magnetic storm sudden commencement (SC) driven by an ICME (top) and gradual (SG) type caused by a CIR (bottom). All storms may not have initial phases. (Slightly modified from Tsurutani et al. 2006)

Relationship Between Magnetic Pulsations and Substorms and Magnetic Storms

Drastic changes occur in magnetospheric magnetic field configuration and plasma populations during substorms and magnetic storms. Therefore, magnetic pulsations that are generated internally, e.g., Pc1 and 2 by electromagnetic ion cyclotron instability, Pc3 and 4 by drift mirror instability, and Pi1 and 2 associated with the formation of substorm current wedges, are directly affected during substorms and magnetic storms. Pc6 magnetic pulsations are also generated during substorms and magnetic storms (Moiseev et al. 2016). Planetary distribution of Pc5 pulsations also undergo changes during magnetic storms (Kleimenova and Kozyreva 2014; Marin et al. 2014). Injection of energetic oxygen ions into the magnetosphere during magnetic storms has a tendency to reduce the frequency of long period-pulsations, especially Pc5s. Further, the ULF wave power increases substantially during magnetic storms. Pc5 pulsations are considered as a factor of accelerating energetic electrons to relativistic energies by radial diffusion during storm main phases (Hudson et al. 1999). It is also possible that such effects occur during storm recovery phases as well (Pilipenko et al. 2010).

Magnetic Storms and Society

Intense ($Dst < -100$ nT) and super-intense ($Dst < -500$ nT) geomagnetic storms create hostile space weather conditions that can harm Earth-orbiting spacecraft and technological systems at ground. High fluxes of relativistic “killer” $\sim$ MeV electrons during such magnetic storms can cause malfunctioning and even failure of sensitive instruments and satellite command systems. Some other deleterious effects are failure of satellite communication and navigational systems, satellite data loss and loss of low earth-orbiting satellites caused by an expanded upper atmosphere. The elevated radiation level can impose a threat to astronauts and jetliner passengers. Geomagnetically induced currents (GICs) can cause damage to power line transformers and corrosion of long pipelines and cables.

Future Outlook

Observations by several spacecraft, such as the Time History of Events and Macroscale Interactions during Substorms (THEMIS), Van Allen Probes (VAP), Cluster, Magnetospheric MultiScale (MMS) mission and others, have led to a new understanding of the properties of ULF waves and their effects on the dynamics of energetic particles in the radiation belt (Sigsbee et al. 2016; Pokhotelov et al. 2016; Paulson et al.

2017; Ren et al. 2019). Korotova et al. (2015) attribute the generation of localized Pc 4 pulsations, with an amplitude of ~ 8 nT in the pre-midnight inner magnetosphere observed by VAP-B on 1 May 2013, due to drift-bounce resonance of hot protons. By analyzing the data from VAP on 8 November 2012, Takahashi et al. (2015) found that plasmaspheric ULF waves showed strong spectral power in the 5–40 mHz band consisting of multiharmonic toroidal waves visible up to the eleventh harmonic. They suggest that most likely this wave activity was driven by the foreshock broadband ULF waves. In another study involving data from Arase spacecraft and ground based stations, Takahashi et al. (2018) proposed that the existence of ULF waves plays an important role in accelerating electrons up to relativistic energies (Murphy et al. 2018). Using a 3-D MHD model for ULF waves, Degeling et al. (2018) have shown that accessibility of dayside ULF wave power to radiation belt electrons is controlled by the convection of plasma density. Rae et al. (2018) have proposed a new mechanism for the loss of energetic radiation belt electrons based on direct modulation of the loss cone by localized compressional ULF waves.

Shi et al. (2018) have analyzed long-lasting (2–3 days) poloidal ULF waves between 5 and 10 mHz observed by multiple satellite and three high-latitude Super Dual Auroral Radar Network (SuperDARN) radars during the recovery phase of a geomagnetic storm on 24–27 January 2016. They suggest the bump-on-tail ion distributions at 1–3 keV to be the source of wave excitation. By using fortuitous multipoint THEMIS spacecraft observations during a rare isolated fast plasma jet impinging on the magnetopause boundary, Archer et al. (2019) have provided an unambiguous direct observation that the resulting magnetopause motion and magnetospheric ULF waves at well-defined frequencies can only be explained in terms of the magnetopause surface eigenmode mechanism (Chen and Hasegawa 1974).

Zhang et al. (2018) have done a statistical study of the Pc5–6 ULF waves in the magnetotail using 8 years of THEMIS data and examined the influence of solar wind parameters and the geomagnetic activity level on the features of these ULF waves. From the analysis of dayside ULF event observed by THEMIS-A on 11 January 2010, Shen et al. (2017) have concluded that the ULF wave was excited by the cavity mode mechanism (Kivelson and Southwood 1985). On the other hand, from a multi-spacecraft study, Wang et al. (2017) have demonstrated that quiet time Pc5 ULF waves are driven by the combined effects of Kelvin-Helmholtz instability and ion foreshock perturbations. Based on in situ observations of chorus and Pc4-Pc5 ULF waves by VAP and ground-based observations of pulsating auroras, Jaynes et al. (2015) have proposed that substorm-driven Pc4–5 ULF pulsations modulate chorus waves, which in turn produce pulsating electron precipitation into the Earth’s atmosphere via cyclotron resonance process.

To conclude, magnetic pulsations play an important role in the transport of the solar wind energy to the magnetosphere, and significantly affect the dynamics of the inner magnetosphere and outer radiation belt during geomagnetic storms. Electromagnetic pulsations and magnetic storms form an important component of space weather. The ground-based studies of magnetic pulsations and magnetic storms offer a unique and simple way of monitoring the conditions in the magnetosphere and solar wind. Measurements of magnetic pulsations and magnetic storms can be utilized for geophysical surveys to probe the subsurface conductivity structure of the Earth.

Definition

eGY. Electronic Geophysical Year. An international science year (2007–2008) celebrating the IGY + 50 anniversary that focused on increasing access to scientific data and information for all people.

Introduction and Concept

Sharing scientific data and information for the common good has long been at the heart of good scientific practice. For the geosciences, the outstandingly successful International Geophysical Year, 1957–1958 (IGY), was a watershed moment in international data sharing. During IGY, in addition to initiating much new research, scientists and member countries worked together to emplace numerous geophysical observatories around the globe and establish a network of World Data Centers for archiving data and for making data available without restrictions.

The Electronic Geophysical Year, 2007–2008 (*eGY*), was conceived in the conviction that the benefits of this “Information Commons” are even greater today than they were 50 years ago. Modern information and communications technologies endow us with unprecedented capabilities for sharing data and information, creating new opportunities for Earth and Space Science Research, and facilitating international coordination to focus effort worldwide, avoid replication, and harmonize standards.

The *eGY* VISION. We can achieve a major step forward in Earth and space science capability, knowledge, and usage throughout the world for the benefit of humanity by accelerating the adoption of modern, visionary practices for managing and sharing data and information.

History

In 1999, the International Union of Geodesy and Geophysics (IUGG) called on its Scientific Associations to propose

activities to mark the 50-year anniversary of IGY. The International Association of Geomagnetism and Aeronomy (IAGA) responded through a resolution passed at the IUGG General Assembly in Sapporo in 2003 to lead an Electronic Geophysical Year.

eGY began on July 1, 2007, and ended on December 31, 2008, exactly 50 years after the start and end of IGY. Support for eGY came from IAGA, IUGG, NASA, the United States National Science Foundation, United States Geological Survey, and the Laboratory for Atmospheric and Space Physics (LASP) of the University of Colorado. In-kind contributions came from the American Geophysical Union (AGU), the National Centre for Atmospheric Research in Boulder, and the volunteer labor of eGY participants.

eGY formally ended on December 31, 2008, exactly 50 years after the IGY ended. eGY achieved its vision primarily through implementation and adoption of virtual observatories. As with the IGY, the mission and goals of eGY are being carried forward through national and international organizations.

Scope

eGY focused on the international science community to achieve a step increase in making past, present, and future geoscientific data (including information and services) rapidly, conveniently, and openly available. The themes of eGY were electronic data location and access, data release and permission, data preservation and rescue, data integration and knowledge discovery, capacity building in developing countries (mainly improving Internet connectivity), and education and outreach. Promoting the development of virtual observatories (VOs) and similar user-community systems for providing open access to data and services was a central feature of eGY.

Operations

Working groups were established to focus effort on each of the eGY theme areas. National eGY groups were particularly active in Canada, China, India, Japan, Russia, and the UK. A Web site served not only as a means of networking among eGY participants but was developed as an information resource for data and information practice and policy.

Presentations, theme sessions, town hall meetings, workshops, and demonstrations of VO technology and working systems were organized at international conferences run by AGU, the Asia Oceania Geophysics Society (AOGS), ICSU's Committees on Data for Science and Technology (CODATA), the Committee on Space Research (COSPAR), the European Geosciences Union (EGU), IAGA, and IUGG. A Virtual Observatories in Geosciences (VOiG) conference was held in Denver in June 2007, with selected papers published in the

April 2008 issue of Earth Science Informatics (<https://link.springer.com/journal/12145/1/1>).

In 2008, an Earth & Space Science Informatics Summit was held in Rome to establish a better understanding and cooperation among various geoinformatics and space science informatics initiatives and programs that are growing rapidly worldwide. A report is available at http://laspl.colorado.edu/media/projects/egy/files/ESI_Summit_Report_final.pdf.

One of the first actions of eGY was to establish a declaration for an Earth and Space Science Information Commons. It states

The Electronic Geophysical Year (eGY) joins with the International Council for Science, the World Summit on the Information Society, and many other bodies in recognizing that knowledge is the common wealth of humanity. We have a shared responsibility to create and implement strategies to realize the full potential of digital information for present and future generations. In the 21st century and beyond, access to digital information and new technologies for information integration and knowledge discovery will influence the free and productive development of societies around the world. Providing ready and open access to the vast and growing collections of cross-disciplinary digital information is the key to understanding and responding to complex Earth system phenomena that influence human survival.

and includes eight articles addressing the major aspects of an Earth and Space Science Information Commons (mirroring the eGY themes).

Achievements

Principal legacies of eGY are (1) stronger awareness of the role that informatics plays in modern research, (2) adoption of virtual observatories and similar systems for accessing data, information, and services, and (3) an expanding infrastructure at the international and national levels. As with IGY, the mission of eGY is being carried forward through existing and newly formed national and international organizations.

Advances in which the eGY effort played a role include:

- Establishment of the Earth & Space Science Informatics Division in EGU
- Establishment of COSPAR's Panel for Informatics
- Establishment of an IUGG Union Commission for Data & Information
- Strengthening of AGU's Earth & Space Science Informatics Special Focus Group to where it is now a formal section within AGU
- IUGG readmission as a member of CODATA and support for a CODATA delegate
- Drafting implementation guidelines for the Global Earth Observing System of Systems (GEOSS) data and information policy
- Formation of an International Polar Year (IPY) Data Policy and Management Subcommittee under ICSU, the World

Meteorological Organization, and CODATA as a CODATA Task Group

- Contributions to development of the IPY Data and Information Service and the Polar Information Commons.
- Formation of a CODATA Task Group: eGY Earth & Space Science Data Interoperability
- ICSU/SCID and SCCID: eGY membership of SCID to review data policy and representation on ICSU's Strategic Coordinating Committee for Information and Data
- eGY-Africa as a contribution to IUGG's Geoscience in Africa initiative

Summary

The Electronic Geophysical Year (eGY) was formed to honor the 50th anniversary of the International Geophysical Year (IGY). It focused on increasing access to scientific data and information, by accelerating the adoption of modern, visionary practices for managing and sharing data and information.

Energy Budget of the Earth

Jean-Claude Mareschal¹ and Claude Jaupart²

¹Centre GEOTOP-UQAM, University of Québec, Montréal, QC, Canada

²Université de Paris Institut de Physique du Globe, Paris, France

Definition

The Earth is a physical system with an energy budget where the outgoing energy must be balanced against all the sources of energy. The planet is not in equilibrium: the difference between the energy flowing out of the Earth and the internal heat production is accounted for by the secular cooling of the mantle and core.

Total Heat Loss of the Earth

The main constraint on the total heat loss of the Earth comes from the many heat flux measurements that have been made both on continents and oceans. Because the continents and the oceans have different thermal structures and because the heat flux data are affected by different biases in each region, it is necessary to analyze separately the continental and the oceanic heat losses (Jaupart et al. 2015).

Continental Heat Flow

There are more than 18,000 reported heat flux measurements on the continents and their margins, not counting measurements made out of equilibrium in oil wells. This is double the number of data in the compilation by Pollack et al. (1993), with many additions by individual researchers. Heat flow data are very unevenly distributed geographically with the majority of them coming from Eurasia and North America. Two large continents, Antarctica and Greenland, are almost unsampled. The raw average of all continental heat flux values is 79.7 mW m^{-2} . This value is biased because the data set includes many data from the USA that were collected for geothermal exploration in anomalously hot regions. The bias is made evident when data from the USA and the rest of the world are analyzed separately: the average is 112.4 mW m^{-2} for the USA vs 65.7 for the rest of the world. One way to remove the bias is by area-weighting: i.e., estimating the average over sufficiently large windows ($1^\circ \times 1^\circ$), and then taking the average of all the windows. It yields an average value for all the continents of 63 mW m^{-2} (Table 1). Multiplying by the continental surface area of $210 \times 10^6 \text{ km}^2$ gives 13.5 TW. An alternative method to calculate continental heat loss is to bin the data by “age”, determine the average value within each age group, integrate

Energy Budget of the Earth, Table 1 Continental heat flux statistics^a

Averages 3° × 3°	61.3	31.3	889

^a μ is the mean, σ is the standard deviation, and N is the number of values

the product of heat flux times the areal age distribution for continental crust. It gives about the same value as the area weighted average.

Oceanic Heat Flow

There are more than 20,000 heat flux measurements reported in the oceans but these data are not directly used to calculate the total heat loss through the oceans. The oceanic heat loss is calculated from a model of cooling of the sea-floor. The measurements are used to determine the parameters of this model. The cooling model of the sea-floor is a direct consequence of the sea-floor spreading hypothesis. It assumes that sea floor forms at mid-oceanic ridges and cools as it moves away from the ridge. The surface heat flux is calculated by solving the heat conduction equation. The solution shows that heat flux q decreases with age τ as:

$$q(\tau) = C_Q \tau^{-1/2}$$

where C_Q depends on the temperature of the magma ascending at the sea floor and on the thermal properties (thermal diffusivity and conductivity) of the cooling lithosphere.

In order to compare the oceanic heat flux measurements with the model, data have been binned by age. Figure 1 shows that the observed heat flux is systematically less than predicted for sea floor ages <60 My and that heat flux is approximately constant and higher than predicted for ages >80 My.

Young Sea Floor

Only the heat that is conducted through the sea floor can be measured. Near the mid-oceanic ridges, where there are large open fractures in the shallow crust, much heat is transported by the movement of hydrothermal fluids. This convective

component of the heat flux accounts for the difference between the observations and the cooling model. At depth, fractures are sealed by the confining pressure and cooling is by conduction only. In regions of the sea floor that are well sealed by sediments, the heat flux observations do fit the cooling model and can be used to determine the constant C_Q . Estimates of C_Q vary between 470 and 510 mW m⁻² My^{1/2}.

Old Sea Floor

After 80My, the heat flux levels off and is higher than calculated for a half space cooling model. The common interpretation is that cooling of the mantle triggers the onset of small scale convection which maintains a constant temperature or heat flux at fixed depth below the sea floor. Experiments designated to measure the heat flux on sea floor older than 100My have shown that it is almost constant and equal to 48 mW m⁻².

Bathymetry

One consequence of the cooling of the sea floor is that the average density of a rock column increases because of thermal contraction:

$$\Delta\rho_m = -\alpha\rho_m\Delta T$$

where α is the thermal expansion coefficient, ρ_m is mantle density, and ΔT is the temperature difference at time τ . The change in bathymetry can be calculated from the isostatic balance condition:

$$\begin{aligned} \Delta h &= \frac{\Delta\rho_m d}{(\rho_m - \rho_w)} = \frac{-\alpha}{C_p(\rho_m - \rho_w)} \int_0^d \Delta T(z, \tau) dz \\ &= \frac{\alpha}{C_p(\rho_m - \rho_w)} \int_0^\tau [q(0, \tau) - q(d, \tau)] d\tau \end{aligned}$$

where C_p is the specific heat of the lithospheric rocks and ρ_w density of sea water. For a half space, $d \rightarrow \infty$ and $q(d, \tau) \rightarrow 0$, we have:

$$\Delta h = \frac{\alpha}{C_p(\rho_m - \rho_w)} \int_0^\tau q(\tau) d\tau$$

It gives:

$$h = h_0 + \frac{2\alpha\rho_m}{C_p(\rho_m - \rho_w)} C_Q \tau^{1/2} = h_0 + C_H \tau^{1/2}$$

The bathymetry of the sea floor fits very well the cooling model for ages less than 80My. For greater ages, the bathymetry becomes flat, confirming that heat supplied at the base balances the heat loss at the surface of the plate (Fig. 2). The

Energy Budget of the Earth,

Fig. 1 Observed and predicted oceanic heat flux as a function of sea floor age. The dotted line is the predicted heat flux for the half space cooling model. The average observed heat flux ($\pm$ one standard deviation) within different age groups is shown by continuous (thin) lines. (Data from Stein and Stein (1994))

constant C_H is related to C_Q and, with standard values for the physical properties of the mantle ($\alpha = 3.1 \times 10^{-5} \text{ K}^{-1}$, $C_p = 1170 \text{ J kg}^{-1} \text{ K}^{-1}$, $\rho_m = 3330 \text{ kg m}^{-3}$, and $\rho_w = 1000 \text{ kg m}^{-3}$), we obtain $C_H/C_Q = 704 \text{ m}^3 \text{ W}^{-1} \text{ My}^{-1}$. Measurements of the depth to the basement on old sea floor have been used to determine a value of $345 \text{ m My}^{-1/2}$ for C_H which translates as $480 \text{ mW m}^{-2} \text{ My}^{1/2}$ for C_Q .

Age Distribution of the Sea Floor

In order to determine the total oceanic heat loss, we have to integrate the heat flux times the areal distribution of sea floor ages. The distribution of sea floor ages has been very well determined from studies of the marine magnetic anomalies (Müller et al. 2008). There are few ages higher than 180 My and the areal distribution appears to decrease linearly with age τ , such that the areal distribution can approximated by:

$$C_A(1 - \tau/180) \quad (1)$$

where τ is age in My (Fig. 3). In order to account for the total area covered by the oceans including the marginal basins ($300 \times 10^6 \text{ km}^2$) the accretion rate $C_A = 3.4 \text{ km}^2 \text{ year}^{-1}$.

Integrating separately sea floor younger and older than 80 My gives:

$$\begin{aligned} Q_{80-} &= \int_0^{80} C_Q \tau^{-1/2} C_A (1 - \tau/180) d\tau = 24.3 \text{ TW} \\ Q_{80+} &= q_{80} \int_{80}^{180} C_A (1 - \tau/180) d\tau = 4.4 \text{ TW} \\ Q_{\text{oceans}} &= 29 \pm 1 \text{ TW} \end{aligned} \quad (2)$$

The cumulative heat loss as a function of age depends strongly on the age distribution (Fig. 4); with a lower accretion rate and a rectangular age distribution, the oceanic heat loss could be as low as 22 TW.

Hot Spots

Hotspots bring additional heat to the oceanic plates. This heat is not accounted for by the plate cooling model and should be added to the heat loss. The extra heat flux is barely detectable, but the heat that has been put in the plate can be estimated from the volume of the swell of the sea floor: it amounts to 2–4 TW.

Energy Budget of the Mantle

The total heat loss at the Earth surface includes continental heat losses 14 TW, cooling of the sea floor, 29 TW, and heat from the hot spots, 3 TW. The resulting value for the total energy loss at the Earth's surface, 46 TW, is not much different from the first estimates by Williams and von Herzen (1974) (Table 2).

Part of this heat is produced by the decay of radio-active elements (U, Th, and K) in the continental crust which has been estimated by multiple and extensive sampling (Rudnick and Fountain 1995; Rudnick and Gao 2014; Jaupart and Mareschal 2014). It is estimated to be 7–8 TW. This leaves 38–39 TW for the mantle heat loss, either by cooling of the sea floor or by conduction through the continental lithosphere. Three main components balance the mantle energy loss: radiogenic heat production in the mantle, heat flux from the core, and secular cooling of the mantle. Other sources (tidal dissipation, gravitational settling, changes in gravitational potential energy due to thermal contraction) contribute less than 1 TW.

Radiogenic Heat Production

Different approaches have been used to estimate the composition of the Earth's mantle and its radiogenic heat production. Earth was formed by accretion of planetesimals in the Solar

Energy Budget of the Earth,

Fig. 2 Worldwide average sea floor bathymetry as a function of age (solid triangle), and predicted bathymetry for a cooling half space (dotted line). Bathymetry data from Crosby and McKenzie (2009)

Energy Budget of the Earth, Fig. 3 Age distribution of the sea floor, not including the marginal basins: distribution from isochrons (solid line); best fit to the distribution (dotted line). (Data from Cogné and Humler (2004))

nebula that have the same origin as the chondritic meteorites. However, the accretion process and the giant impact that formed the Moon have modified Earth’s composition relative to the meteorites. Estimates of mantle composition rely on comparing elemental ratios on Earth and meteorites, to infer the composition of bulk silicate Earth (BSE), i.e., the mantle and crust. Another method assumes that compositional trends in meteorites and mantle rocks record processes in the solar nebula and the mantle, and that they will intersect at the composition of their common source. Both methods yield a heat production of ≈ 20 TW for BSE. Accounting for the radio-elements that have been stored in the continental lithosphere leaves 13 TW in the convecting mantle. It is useful to compare the mantle heat production to its heat loss: this ratio is referred to as the *Urey ratio* of the mantle. It is estimated to be in the range 0.12–0.49 with a preferred value of 0.29.

A lower bound for mantle heat production can be obtained from the composition of the rocks that are extracted from the

Energy Budget of the Earth, Fig. 4 Cumulative total heat loss of the sea floor for three different distributions of the sea floor age: the present triangular distribution, triangular distribution with twice the present spreading rate and oldest sea floor 90My, rectangular distribution with oldest sea floor 180My and spreading rate half of present. The total oceanic area is 300×10^6 km², and $C_Q = 490$ mW m⁻²My^{-1/2}; for ages >80My, heat flux is 48 mW m⁻²

Energy Budget of the Earth, Table 2 Estimates of the continental and oceanic heat flux and global heat loss

	continental mW m ⁻²	Oceanic mW m ⁻²	Total TW
Williams and von Herzen (1974)	61	93	43
Davies (1980)	55	95	41
Slater et al. (1980)	57	99	42

Davies and Davies (2010)	71	105	47
Jaupart et al. (2015) ^a	65	94	46

^aThe average oceanic heat flux does not include the contribution of hotspots. The total heat loss estimate does include 3 TW from oceanic hotspots

mantle to form the sea floor. This only gives a lower bound because it does not take into account a possible hidden reservoir that has not been tapped by the extraction of the MORBs. This estimate is 11 TW for the mantle; accounting for the heat production in the continental lithosphere gives a total radiogenic heat production higher than 18 TW for BSE. These various estimates are summarized in Table 3.

Heat Flux From the Core

Some authors have assumed that the heat flux from the core is equal to the total heat transported by the hotspots. There is no reason that it should be so. The heat carried away by hotspots originating at the core mantle boundary must be less than the core's output. This gives a lower bound of 4 TW. A different bound can be obtained by calculating the minimum heat flux that would be conducted along an adiabat in the core. The core is thought to have a high thermal conductivity ($\approx 80 \text{ W m}^{-1} \text{ K}^{-1}$) and the heat flux conducted along the adiabat is 40 mW m^{-2} , with a total output of 5 TW. More recent measurements and calculations of the core thermal conductivity (Pozzo et al. 2012; Gomi et al. 2013) have led to much higher values of thermal conductivity than previously thought, in the range $130\text{--}200 \text{ W m}^{-1} \text{ K}^{-1}$. Such values

imply a total core heat loss between 9 and 17 TW. How much energy is required to power the geodynamo has been much debated. Present estimates vary within a wide range (9–17 TW) with an average value of 11–12 TW (Nimmo 2015; Buffett 2015).

Secular Cooling

Table 4 compares different ways of breaking down the energy budget of the mantle. Stacey and Davis (2008) add the radio-activity in the continental crust to that of BSE and thus overestimate the total heat production. Both Stacey and Davis (2008) and Davies (1999) assumed that all the heat from the core is carried away by the hotspots, although the hotspots provide only a weak lower bound on core heat flow.

The difference between the total mantle energy loss and the inputs from the core, radio-activity, and other sources, $38\text{--}11\text{--}11 = 16 \text{ TW}$, must be accounted for by the secular cooling of the mantle. Because of the large uncertainties on the core heat loss and on mantle heat production, the range for mantle cooling is implausibly wide (Table 4). The present mean value of 16 TW corresponds to a mantle cooling rate of $\approx 100 \text{ K Gy}^{-1}$. Mantle temperatures can be calculated from the composition of the Mid oceanic ridge basalts (MORB).

Energy Budget of the Earth, Fig. 5 Temperature of the source of nonarc basaltic rocks as a function of age. The vertical arrow at zero age shows the range of mantle potential temperature estimates. Most of the data fall between the 50 K Gy⁻¹ and 100 K Gy⁻¹ lines (Herzberg et al. 2010). The convergence of the trend to the present range of mantle temperatures gives confidence in these results

Petrological studies on nonarc basaltic rocks (Herzberg et al. 2010) suggest a cooling rate in the range 50–100 K Gy⁻¹ (Fig. 5). The present cooling rate falls near the high end of the range obtained in the petrology studies. There is a scatter in the estimated mantle temperatures, but there is a trend

Energy Budget of the Earth, Fig. 6 Proposed breakdown of the present energy budget of the Earth. With heat production in the continental lithosphere, mantle heat production, and core heat loss constrained, the mantle cooling rate is adjusted to fit the total energy loss determined from surface heat flux, allowing an implausible wide range

indicating lower cooling rate in the past and possibly heating of the mantle before 3 Ga. These differences between the present and secular rates of cooling raise interesting questions about long term changes in the energy budget (Fig. 6).

Present and Long Term Cooling Rates

Is the present rate of energy loss equal to the long term rate? The energy lost through the sea floor depends on the age distribution of the sea floor. It is likely that the energy lost through the sea floor fluctuates with the super continent cycle and that the present energy loss is different from the long term mean. The second point is that radioactive heat production in the mantle was higher in the past than now for two reasons: one reason is the rundown of radio-elements, the other is the extraction of continental crust that removed radio-elements from the mantle. Finally, the heat loss from the mantle depends on the total continental area as much more heat escapes through the sea floor than through the continental lithosphere. The input from the core may also oscillate and have been different in the past, when the frequency of geo-magnetic reversals was lower than in recent times.

The relative importance of these effects remains difficult to assess because we do not precisely know how the volume of continental crust changed with time, but Fig. 7 presents one plausible thermal history of the mantle with the added

assumption that the mantle heat loss oscillates by ± 7 TW over a period of 400My corresponding to the supercontinent cycle.

Perspectives

The past years have seen the development of underground neutrino observatories that can detect geo-neutrinos, i.e., neutrinos from the decay of U and Th in the Earth, which appeared to be a new avenue for estimating the radio-genic power of the mantle (Dye 2012). First results from 2 land observatories (Kamioka, in Japan, and the small Borexino detector, in Italy) have yielded an estimated 18 TW total heat production for the crust and mantle but still leave a large uncertainty due to measurements errors and the poorly estimated crustal contribution to the measured neutrino activity (Kamland collaboration, (Gando, A. and 45 collaborators) 2013; Borexino collaboration group 2013).

New estimates of the core thermal conductivity imply a much higher rate of cooling (>10 TW) for the core than previously thought. These values of thermal conductivity will need further confirmation, but they narrow down the estimated core heat flux and consequently imply tighter constraints on the mantle energy budget.

Energy Budget of the Earth, Fig. 7 Effect of fluctuations of oceanic heat loss over a supercontinent time-scale of $\tau_w = 400$ My on the secular thermal evolution of the mantle, from Labrosse and Jaupart (2007). The model calculations rely on a simple parametrization of sea floor spreading that leads to a weak secular variation of oceanic heat loss. Heat loss fluctuations due to changes of sea floor spreading are superimposed on the secular trend. These changes occur on a time-scale that is short compared to that of the secular trend and leave almost no trace on mantle temperatures. Top panel (a): the various contributions to the Earth's energy budget that are used in the calculation. Bottom panel (b): predicted evolution of the average mantle temperature through time

Summary

The Earth loses energy as heat flows out through its surface. The total energy loss of the Earth has been estimated at 46 ± 2 TW, of which 14 TW come through the continents while 32 TW come from the cooling of the sea floor. After removing the heat production of radio-active elements in the continental lithosphere (8 TW), the energy loss from the mantle is 38 TW. Three main components balance the mantle energy budget: Heat flow from the core (9–17 TW), radiogenic heat production in the mantle (9–17 TW), and the secular cooling of the mantle (4–29 TW). The uncertainty on the exact contribution of each component is much larger than that on the total heat loss. The best estimate of the present cooling rate of the mantle (110 K Gy^{-1}) is the upper range of estimates from petrology of the secular cooling rate for the past 3Gy. The present cooling rate may be different from its long term average because of variations in sea floor spreading rates and higher mantle heat production in the past.

Energy Partitioning of Seismic Waves

Kalachand Sain

Wadia Institute of Himalayan Geology, Dehradun, India

Synonyms

Partitioning – conversion

Definition

When an incoming P-wave strikes an interface between two isotropic homogeneous elastic media at an angle other than the vertical, a portion of the P-wave energy is converted into S-wave energy, which gets reflected and transmitted in the same way as the P-wave does. This is known as the energy partitioning of seismic wave.

Snell's law: The angles of incidence, reflection, and transmission, as shown in Fig. 1, are related by the Snell's law, which says that the ratio of sines of angles of incidence, reflection, and transmission to velocities of respective media across the interface is constant. In seismology, this constant is defined as the ray parameter, R_p as:

Energy Partitioning of Seismic Waves, Fig. 1 Ray diagram for the partition of a plane wave energy at a horizontal interface

$$\frac{\sin \theta_1}{V_{P1}} = \frac{\sin \theta_2}{V_{P2}} = \frac{\sin \phi_1}{V_{S1}} = \frac{\sin \phi_2}{V_{S2}} = R_P \quad (1)$$

where V_P , V_S , and ρ are the P-wave velocity, S-wave velocity, and density, respectively, and subscripts 1 and 2 represent the first and second layers, respectively.

Reflection and transmission coefficients: A reflection coefficient describes either the amplitude or the energy of a reflected wave relative to an incident wave; similarly a transmission coefficient describes either the amplitude or the energy of a transmitted wave relative to an incident wave. When a plane wave strikes a horizontal interface vertically (i.e., at normal incidence), the reflection coefficient, R_C and the transmission coefficient, T_C are defined as:

$$R_C = \frac{Z_2 - Z_1}{Z_2 + Z_1} \quad (2)$$

$$T_C = \frac{2Z_1}{Z_2 + Z_1} \quad (3)$$

where Z_1 and Z_2 are the acoustic impedance (P-wave velocity multiplied by density) of the first and second media, respectively.

Zoeppritz equation: When the seismic ray obliquely strikes the interface (Fig. 1), separated by three elastic parameters (V_P , V_S , and ρ) on either side, the R_C and T_C as expressed by equations (2) and (3) are not valid. The reflection and transmission coefficients or amplitudes of both P-P and mode converted P-S-waves as a function of angle can be derived using the Zoeppritz equations (Zoeppritz 1919) that can be easily expressed through a matrix (Waters 1981) as:

$$Q = P^{-1}R \quad (4)$$

where P is a 4×4 square matrix and, R and Q are 4×1 column matrices whose elements are shown as:

$$P = \begin{bmatrix} \sin \theta_1 & \cos \phi_1 & -\sin \theta_2 & \cos \phi_2 \\ -\cos \theta_1 & \sin \phi_1 & -\cos \theta_2 & -\sin \phi_2 \\ \sin 2\theta_1 & \frac{V_{P1}}{V_{S1}} \cos 2\phi_1 & \frac{\rho_2 V_{S2}^2}{\rho_1 V_{S1}^2} 2 \sin \theta_1 \cos \theta_2 & -\frac{\rho_2 V_{P1} V_{S2}}{\rho_1 V_{S1}^2} \cos 2\phi_2 \\ \cos 2\phi_1 & -\frac{V_{S1}}{V_{P1}} \sin 2\phi_1 & -\frac{\rho_2 V_{P2}}{\rho_1 V_{P1}} \cos 2\phi_2 & -\frac{\rho_2 V_{S2}}{\rho_1 V_{P1}} \sin 2\phi_2 \end{bmatrix} \quad (5)$$

$$Q = [R_{PPR} \ R_{PSVR} \ R_{PPT} \ R_{PSVT}]^T \text{ and} \quad (6)$$

$$R = [-\sin q_1 \ -\cos q_1 \ \sin 2q_1 \ -\cos 2f_1]^T$$

where R_{PPR} and R_{PSVR} are the reflection coefficients and, R_{PPT} and R_{PSVT} are the transmission coefficients of P-P and mode converted P-S waves, respectively.

Figure 2(a) displays the coefficients of reflections and transmissions for P-P and converted P-S waves as a function of incident angles (θ) as per equation (4) for the model shown in the figure itself. At zero angle or offset, the R_C for P-P wave is mainly governed by the P-wave velocity. However, at nonzero angle or offset, its value depends on both the P and S wave velocities. The nature and amplitudes of curves vary with the elastic parameters across the interface (Fig. 2b). These elastic parameters mainly depend on the mineralogical constituents, fluids, pressure, temperature, etc.

Approximation to the Zoeppritz equation led to an elegant method of reducing these curves based on just two parameters. According to Shuey (1985), the P-wave reflection coefficient, $R_C(\theta)$ for an incidence angle (θ) up to $\sim 30^\circ$ can be expressed as:

$$R_C(\theta) \approx A + B \sin^2 \theta \quad (7)$$

where A is the intercept or normal incidence reflection coefficient, and B is the gradient.

$$A = \frac{1}{2} \left(\frac{\Delta V_P}{V_P} + \frac{\Delta \rho}{\rho} \right), B = A A_0 + \frac{\Delta \sigma}{(1 - \sigma)^2} \quad (8)$$

$$A_0 = B_0 - 2(1 + B_0) \frac{1 - 2\sigma}{1 - \sigma}, B_0 = \frac{\Delta V_P / V_P}{\Delta V_P / V_P + \Delta \rho / \rho},$$

$$V_P = (V_{P2} + V_{P1})/2, V_S = (V_{S2} + V_{S1})/2, \rho = (\rho_2 + \rho_1)/2,$$

$$\Delta V_P = (V_{P2} - V_{P1}), \Delta V_S = (V_{S2} - V_{S1}), \Delta \rho = (\rho_2 - \rho_1),$$

$$\Delta \sigma = (\sigma_2 - \sigma_1), \sigma = (\sigma_2 + \sigma_1)/2, \sigma_1 = (5V_{P1}^2 - V_{S1}^2) / (V_{P1}^2 - V_{S1}^2)$$

Equations (7) and (8) are valid up to high A for a negative impedance contrast across an interface, and to about $A = 0.2$ for a positive impedance contrast. Since 30° angle corresponds to the maximum angle that we generally encounter

Energy Partitioning of Seismic Waves, Fig. 2

(a) Reflection and transmission coefficients as a function of incidence angles for the model shown inside. (b) Reflection and transmission coefficients as a function of incidence angles for the model shown inside in which the layer parameters for model in (a) are interchanged

in normal seismic data acquisition, this approximation is widely used to determine the amplitude versus offset (AVO) attributes for the interpretation of seismic data.

AVO response for a realistic earth model: The reflections from various subsurface interfaces exhibit a wide range of AVO characteristics that depend upon the rock types and fluid contents. From the field data, the amplitudes and offsets of reflected phases can be converted into reflection coefficients and angles (Warner 1990). By modeling using the Zoeppritz equation, we can derive various elastic parameters (Ojha and Sain 2007, 2008; Arun et al. 2018, 2020) or Poisson ratio (σ) that can be used for the exploration of gas hydrates or hydrocarbons. Any overpressure in the trapped gas can also be known from the AVO anomaly (Tinivella 2002; Dash et al. 2004) that helps in avoiding drilling hazard. In oil industries, the AVO attributes have gained considerable popularity for hydrocarbon detection, lithology identification, and reservoir characterizations or fluid parameter analysis (Dahl and Ursin 1992; Castagna and Backus 1993; Castagna et al. 1998; Dahroug et al. 2018) due to the fact that seismic amplitudes at interfaces are affected by the variations of physical properties just above and below the interfaces. Ojha et al. (2010) have demonstrated through a field example that a plot of A versus B coupled with rock physics modeling can be used as a rapid tool for detecting free-gas below a bottom simulating reflector or BSR, and quantifying the amount of gas-hydrate and free-gas along a seismic reflection profile.

The gas-sand detection is the most promising application of AVO analysis. The characteristically low V_P/V_S ratio or σ of gas sand is expected to be differentiated from other low-impedance layers, such as coals and porous brine or oil sands. Rutherford and Williams (1989) have defined three distinct classes of gas-sand AVO anomalies (Figs. 3 and 4) mainly based on the intercept, A and gradient, B attributes.

The Class 1 is a high impedance sand anomaly and occurs when the normal-incidence P-wave reflection coefficient is strongly positive. This shows a strong amplitude decrease with offset and a possible phase change at far offset. The Class II anomaly occurs when the gas sand has similar impedance to the neighboring shale. For the gas sand scenario, the normal incidence reflection coefficient is close to zero and becomes negative at larger offsets. The Class III is the classic Gulf of Mexico AVO anomaly where gas sand has low impedance compared to shale. The normal incidence reflection coefficient is negative and becomes more negative as offset increases. The “bright spot” is associated with the Class III AVO anomaly and can be used as a direct indicator for hydrocarbons.

If the rock overlying the reservoir has a velocity appreciably lower than that of the reservoir itself (e.g., carbonate reservoir capped by shale), the effect of hydrocarbon is to decrease the impedance contrast and reduce the reflection coefficient producing a “dim spot.” Class I and Class II AVO anomalies can produce the reverse effect. When the rock overlying the reservoir has a velocity slightly smaller

Energy Partitioning of Seismic Waves, Fig. 3 Seismogram showing AVO response for three classes of gas-sand anomalies and a typical reservoir showing the Poisson ratio

Energy Partitioning of Seismic Waves, Fig. 4 AVO curves for three classes of gas-sand anomalies.

than that of the reservoir rock, lowering the impedance of reservoir rock by hydrocarbons may invert the sign of reflection, producing a polarity reversal. The sand types and presence of gas can be identified from the classical A-B crossplot. Recently, Hussein et al. (2020) illustrated this by categorizing different gas zones based on crossplot between A and B seismic attributes using a data set in the El-Mansoura field, onshore Nile Delta in Egypt.

Summary

Because of energy partitioning, we can record both P- and S-waves using multicomponent sensors, and derive both the P- and S-wave seismic velocities and their ratio (V_p/V_s), which can provide reliable and more accurate information than an individual wave can do. The AVO tools have been very efficient in oil industry for the identification of lithology and delineation of fluids content. The AVO response can also be utilized in determining the overpressure, which is prerequisite to avoid any drilling hazard.

Acknowledgments I am grateful to the Director, Wadia Institute of Himalayan Geology for permission. The Ministry of Earth Sciences, Govt. of India is thankfully acknowledged for sponsoring the gas-hydrate research at CSIR-NGRI, Hyderabad, India.

Equatorial Electrojet

Archana Bhattacharyya

Indian Institute of Geomagnetism, Navi Mumbai, India

Definition

The equatorial electrojet (EEJ) is a narrow band of intense electric current that flows along the dip equator in the day side ionospheric E region with peak current density at an altitude of around 105 km.

Cause

Electrical conductivity of the partially but significantly ionized upper atmosphere of Earth is anisotropic due to presence of Earth's magnetic field. In the ionospheric E region, movement of electrons in response to an electric field is influenced by the geomagnetic field, whereas for the heavier ions, collisions with neutral particles have much greater influence. This difference in the behavior of electrons and ions gives rise to a large Hall conductivity in the E region. Atmospheric tides, driven mainly by solar heating and to a lesser extent by the gravitational pull of moon, cause the neutral atmosphere to undergo global-scale oscillations, with harmonic periods of a day. These oscillations, through ion-neutral collisions, set the electrically conducting ionospheric plasma into motion, thereby generating an electric field in E region due to dynamo action in the presence of the geomagnetic field. At the dip equator, where the geomagnetic field is horizontal and northward directed, an eastward electric field in magnetic east-west direction drives a downward Hall current, which is restricted due to limited vertical extent of the E region. This causes charges to accumulate producing an upward polarization electric field much larger than the original eastward electric field in a region where Hall conductivity is much larger than Pedersen conductivity. The upward electric field now drives an eastward Hall current that greatly exceeds the original eastward Pedersen current. Together these eastward currents constitute the normal equatorial electrojet (EEJ), which depends on an effective Cowling conductivity (Forbes 1981; Yamazaki and Maute 2017).

Characteristics of the EEJ

The EEJ has been observed using magnetometers on the ground as well as on board rockets and low Earth orbiting

satellites. Geomagnetic field variations recorded at observatories near the dip equator and at low-latitude observatories outside the influence of the EEJ but in the same longitude zone show a typical enhancement of about 40–100 nT in the horizontal component of the geomagnetic field during daytime at the equatorial location, due to the EEJ. Observations by satellites such as Ørsted, SAC-C, and CHAMP have yielded information about spatial features of the EEJ (Olsen and Stolle 2012). Assuming the EEJ to flow in a thin sheet, average current density estimated from CHAMP data is 0.19 A/m, while latitudinal extent of eastward currents of the EEJ at noontime is estimated to be about $\pm 2^\circ$ around the dip equator, where the current peaks. Smaller westward return currents are found to peak at approximately $\pm 5^\circ$ from the dip equator. It is yet to be established how return currents close the EEJ. CHAMP data has shown the EEJ to be correlated over a short longitude range of approximately $\pm 15^\circ$. Figure 1a shows the daily variation of EEJ strength, ΔH_{EEJ} , computed from measurements at a dip equatorial location and an off-equatorial location outside the influence of the EEJ, in the Indian longitude zone, on International Quiet (IQ) days of the year 2001. The EEJ shows considerable day-to-day variations, even for magnetically quiet days. On some days, the magnetic signatures recorded at observatories or by satellites indicate a daytime current flowing in the westward direction. This is called the counter electrojet, a phenomenon not yet understood (Rastogi 1989). The EEJ also varies on seasonal and solar cycle time scales. Role of solar EUV flux in altering ionospheric electrical conductivity and contribution of variability of atmospheric tides in changing the dynamo electric field can be seen in a principal component analysis of the daily variations of EEJ in the Indian region (Bhattacharyya and Okpala 2015). First three principal components (PCs) for IQ days of 14 years, 1999–2012, are shown in Fig. 1b. These three PCs together account for 96% of the variance in ΔH_{EEJ} during this period. Observed daily 10.7 cm solar flux, which is used as a proxy for solar EUV radiation responsible for ionizing Earth's upper atmosphere, is plotted in top panel of Fig. 1c for the days considered. Corresponding daily amplitudes for PC1, which contributes the most to day-to-day variations of quiet time EEJ around 11 LT, are plotted in bottom panel of Fig. 1c. PC1 amplitudes show a semiannual variation with equinoctial maxima, mostly due to upward propagating tides generated in the lower atmosphere, modulated by solar EUV flux. Geomagnetic storms and substorms can also alter the equatorial ionospheric electric field. The EEJ thus reflects changes in equatorial ionospheric electric field, due to both forcing from lower atmosphere and forcing from magnetosphere above due to transient events on the sun.

Equatorial Electrojet, Fig. 1 (a) Daily variation of EEJ strength, ΔH_{EEJ} , in Indian region on IQ days of the year 2001, as a function of local time (LT) at 75°E longitude. (b) First three principal components, PC1, PC2, and PC3, computed using ΔH_{EEJ} for 794 IQ days from the

years 1999–2012. (c) Top – Observed daily 10.7 cm solar flux, Sf (in units of $10^{-22} \text{ W m}^{-2} \text{ Hz}^{-1}$) for the IQ days considered; bottom – Corresponding daily amplitudes for PC1 (in nT)

Uses of EEJ Observations

Electric field in the equatorial ionospheric E region plays a major role in determining spatial distribution of ionospheric plasma throughout the low-latitude ionosphere. This can be seen from global maps of vertical total electron content (TEC) of the ionosphere derived from records of radio signals transmitted from the Global Navigation Satellite Systems (GNSS). Ionospheric plasma distribution affects the performance of satellite-based communication and navigation systems such as GNSS. The EEJ is a useful indicator of the state of the low-latitude ionosphere during daytime. In processing of data collected in magnetic surveys as a part of geophysical exploration for natural resources, it is necessary to remove the diurnal variation in the geomagnetic field due to the EEJ. The EEJ is also a natural source for electromagnetic induction studies. However, its latitudinal extent sets a limit on the depth within the Earth to which electrical conductivity can be determined using temporal variations of the EEJ.

Fault zone normal and leaky modes; Fault Zone Trapped Waves (FZTW); F_g , F_L , F_R , and F_ϕ

Definition

Fault Zone Guided Waves (FZGW) are elastic waves largely confined to zones of low seismic velocities associated with faults. On seismograms, they are designated by the phase name F_g . FZGW can be viewed as resulting from the constructive interference of P and/or S body waves, either totally or partially reflected from edges of the fault damage zone where seismic velocities increase relative the velocities of the fault core. They can also be modeled as the normal and leaky modes of this same structure.

F_g waves on large faults are analogous to seismic surface and in-seam waves (Aki and Richards 1980; Dresen and Rüter 1994). For those familiar with the former, the Earth structure giving rise to F_g waves can be visualized with the diagram shown in Fig. 1. Like surface waves, F_g waves can be divided into Love and Rayleigh type modes, F_L and F_R , depending on their motion with respect to the plane of the fault. The Love type motion is parallel to this plane, whereas the Rayleigh types include motions perpendicular to the plane. Leaky mode F_g waves have also been observed, the first being PSV F_ϕ waves, also with plane-perpendicular motions (Ellsworth and Malin 2011).

The frequency contents and propagation velocities of F_g waves are functions of the geometry of a fault zone's P and

S wave velocity structure. Modeling of F_L , F_R , and F_ϕ waves in major faults shows these zones to be on the order of 10–200 m wide, with velocity reductions between 5% and 20% of the surrounding rock, with some instances of both much narrower and wider damage zones and up to 50% velocity reductions (e.g., Li et al. 2016, 2019; Catchings et al. 2016). These characteristics have been used to help understand the nature of earthquake rupture. The low-velocity channel causes F_g waves to exhibit frequency-versus-velocity dispersion, with phase velocities of low frequencies being higher than those of higher frequencies. F_g -group velocities can thus show Airy Phase cutoffs.

The geometric spreading of FZGW energy is cylindrical, as opposed to spherical. However, F_ϕ waves attenuate more rapidly due to their leakage of P-S converted waves. Fault-zone discontinuities, heterogeneities, and anisotropies can distort or completely disperse or attenuate F_g waves. As a result, fault segmentations and other kinds of offsets can disrupt F_g wave propagation, a fact that has been used to map fault-zone lateral and vertical extents. However, the ultimate depths to which F_g -supporting low-velocity zones exist continue to be a source of investigation. Current observational limits ranging between a small fraction of a km and 12 km, as in the cases of the San Andreas and San Jacinto faults in California.

A Short and Recent History of Fault Zone Guided Wave Seismology and Controversies

Two years after the 28 September 1966 M 6.0 Parkfield, California, earthquake on the San Andreas Fault, Keiiti Aki presented a model of the earthquake's strong motion close to the fault. (Aki and Paul Richards wrote the 1980 *Quantitative Seismology* text most currently active seismologists used in their university educations.) Recorded a few tens of meters off the SAF in Chalome Valley the waveform motion included a

Fault Zone Guided Waves, Fig. 1 A way of visualizing fully trapped a Fault Zone Guided Wave by analogy to the generation and propagation of ordinary seismic surface waves. (a) Mirror image, half space, cross sections showing (1) a low-velocity weathering layer over (2) a faster layer, which in turn overlies (3) an even faster basement. The z axis points down into the earth and the x axis along the ground. Surface waves (4 and 5), fully trapped in the low-velocity layers (1 and 2), can be described as interfering plane waves that propagate in the x direction in the lower velocity layers and exponentially die in the z direction in the higher velocity layers (2 and 3). (e.g., see <https://www.acs.psu.edu/drussell/Demos/EvanescenceWaves/EvanescenceWaves.html>.) These waves can be excited by near-surface sources (such as explosions) and earthquakes at appropriate depths. They can also be described as normal modes of the velocity structure. (b) Rotating the cross sections in (a) as

indicated and joining them at their former land surfaces creates two vertical low-velocity channels sandwiched between two higher velocity quarter spaces. The former near-surface weathering layer (1) now represents the core of a fault embedded in a broad damage zone (2). In this case, the interfering plane waves propagate along the z direction and exponential decay is along the x direction. As shown in Fig. 3, especially in the event that the P-wave velocities in the core approach the S-wave velocities in the damage zone, a propagating plane wave may leak out of this boundary as well. A similar situation can occur between the damage zone and the high-velocity quarter spaces. These signals form the leaky modes of this velocity structure. Inseam guided waves can also be visualized by turning diagram (b) 90° clockwise and relocating the ground surface on top of the upper high-velocity layer

Fault Zone Guided Waves, Fig. 2 Strong motion record from the 1966 Parkfield Earthquake (Aki 1968). Shown is the horizontal transverse component perpendicular to the San Andreas Fault rupture plane in Chalome Valley. The underscore indicates a normally dispersed low-frequency pulse that arrived much later than Aki's models of seismic waves in faults described. Aki was aware of this – and bothered by it – and eventually, with the aid of borehole stations directly on the San Andreas Fault at Middle Mountain, was able to resolve its origin as Fault Zone Guided Waves (Li et al. 1990). (Figure modified from Aki (1982)

late, unaccounted-for, wave train (Aki 1968; Fig. 2). Aki was aware of it, and in his reflective way, simply commented that the model did not match the data, but the Earth was not at fault (K. Aki, personal comment, 1989).

Around this same time, Karen McNally, working in Tom McEvilly's seismology group at University of California Berkeley, and then later as Professor at UC Santa Cruz, also noted near-fault, late-arriving phases. Often these signals had larger amplitudes and lower frequencies than any of the direct body waves (K. McNally, personal communication, 1990). Generated by deep microearthquakes, these seismic waves were decidedly not ordinary surface waves trapped in near-surface, low-velocity layers.

Relatively low frequency and apparently normally dispersed, the puzzle of these near-SAF fault signals began to unravel when numerous examples were found in near-fault borehole recordings from Middle Mountain, north of Parkfield. The first published observational report on these examples was by Yong-Gang Li, with associated theoretical analysis by Yehuda Ben-Zion, both of whom were working in Aki's lab at USC (Li et al. 1990; Ben-Zion 1990). (For a reference to borehole seismic observations at Parkfield and elsewhere see: Malin et al. 1989; https://seismo.berkeley.edu/bdsn/hrsn_overview.html; Ellsworth and Malin 2011; Bohnhoff and Malin, in this volume. Earlier work with models and observations suggestive of the existence of FZGW were presented by Cormier and Spudich 1984).

Li and Ben-Zion each went on to publish numerous fault guided wave observational and theoretical studies, references to which can be found variously in Li (2018) and Ben-Zion (1998). Li and Ben-Zion also landed on opposite sides of an amicable debate on the depth at which F_g waves could

originate, with the implication being the depth to which velocity contrasts of the sort shown in Fig. 1 extend. This question is reviewed on both sides by Yang (2015).

Ben-Zion et al. (2007), for example, argue that F_g -supporting velocity contrasts do not extend much deeper than 5 km at most, with the most definitive supporting data coming from the San Jacinto fault in southern California (Qin et al. 2018). The apparent discrepancy between F_g -generating events located deeper than 5 km being resolved by scattering or other types of coupling in shallower low-velocity fault zones.

Alternatively, claims of F_g waves originating directly from low-velocity zones extending to 7.2, 10.6, 11.7, and 12.6 km depths along the San Andreas are presented by Ellsworth and Malin (2011), Li and Malin (2008), and Wu et al. (2010).

Perhaps these differences originate in the location and maturity of the fault supporting the guided wave as opposed to complicated wave propagation and scattering effects.

Types of Fault Zone Guided Waves and Their Particle Motions

When fully trapped by total reflection from either the fault zone's internal velocity structure or the damage zone's edges, F_g waves can be separated into two types of signals (Malin et al. 1996; Fig. 3a, b). Analogous to the case of ordinary surface waves and their PSV and SH relation to the ground surface, this separation is based on wave motions with respect to the plane of the fault zone. Fault guided wave motions parallel to the fault plane consist of constructively interfering S-waves and are known as Love types, which are designated by the phase name F_L . Motions with components perpendicular to the damage plane are known as Rayleigh types and are designated as F_R waves. Both F_L and F_R phase velocities range between the highest and lowest S-wave velocities of the fault zone (e.g., Ben-Zion 1998).

Fault guided waves can also become only partially trapped in a damage zone, leaking part of their energy out of this zone. As a result, these signals attenuate more rapidly (Fig. 3c).

Fault Zone Guided Waves, Fig. 3 Upper: (a) Love type motion (F_L) in a low-velocity fault zone between half spaces. The circles with a dot and cross represent back and forth motion parallel to the plane of the fault zone. (b) Motion for the Rayleigh type (F_R) guided wave, the double ended arrows signifying its constructively interfering P and S components. (c) Motion for the leaky mode (F_ϕ) guided wave.

Lower: Fault Zone Guided Waves observed in the San Andreas Fault Observatory at Depth (Ellsworth and Malin 2011). Each wave type is identified by its direction of motion with respect to the plane of this fault. The box on the left is expanded on the right to better reveal the normal dispersion of the F_ϕ wave train. (Figure modified from Ellsworth and Malin 2011)

Currently, due probably to this attenuation, only P-to-S type leaky F_g waves have been recognized in seismograms. In fact, P-to-S type leaky F_g waves have only been recorded in deep boreholes drilled into major faults like the San Andreas Fault (Ellsworth and Malin 2011) and in high-resolution, dense, multichannel fault observatories (Qin et al. 2018).

This phase, known as an F_ϕ wave, is most strongly excited when the S-wave velocity outside either the fault zone core or the damage zone is near the P-wave velocity inside it. Its particle motion still has fault-zone perpendicular components, but the F_ϕ wave propagates faster than the wall-rock-velocity of the direct S-wave. Other types of leaky F_g waves, originating from the many organ pipe modes of a given fault zone's velocity structure, have yet to be documented. Such rapidly attenuating signals are likely to be observed only in boreholes drilled close to their fault zone sources and on dense, multisensor, arrays covering the fault core, damage zone, and surrounding country rock.

The Effects of Fault Geometry, Velocity Structure, Anisotropy, and Heterogeneity

Bracketing the current endmembers of FZGW observation-modeling in 1-D and 3-D velocity structures are the studies of Igel et al. (2002), Jahnke et al. (2002), and Gulley et al. (2017a, b). The former two studies deal with sources and receivers on and off layered fault zones, restrictions along faults, low-velocity zone offsets, and 3-D heterogeneity. Their results investigating on- and off-fault sources were expanded upon by Fohrmann et al. (2004). Some of the fundamental findings include:

- Lateral and vertical fault-zone discontinuities more significantly alter F_g waveforms
- Moderate velocity gradients, small heterogeneities, and changes in width have little effect
- Sources outside and below shallow fault zones (<5 km) can generate F_g signals in faults
- Alternatively, the shallow part of a deep fault zone allows for the trapping of F_g signals

The two papers by Gulley et al. discuss modeling methods and effects of faults with cross-fault velocity gradients rather than layers, fault plane parallel isotropy and anisotropy. They find that:

- Fault models with exponentially decaying velocities toward their cores differ from three-layer ones with the Airy phases being absent
- For small wall velocity contrasts, F_g in transverse-isotropy faults depend on fault parallel S-velocities

- Fault-aligned structures enhance the amplitude and length of F_R
- Moving sources or receivers away from the fault removes higher frequencies F_R first

All these facets of F_g -waves impact the use of observational data to infer fault-zone properties and their relationship to earthquake rupture processes (e.g., Kuwahara and Ito 2002).

Conclusions

Whereas observations and modeling of basic F_g waves F_L , F_R , and F_ϕ in relatively complex fault structures is now well established, other types of modes have yet to be discovered and described. It is likely that other types of leaky mode F_g waves will attenuate rapidly away from their earthquake sources. This makes it likely that leaky mode F_g waves will be most readily observed in deep boreholes drilled close to event hypocenters or then on dense arrays of seismographs on shallow faults. Currently, forward modeling appears to be the preferred method for extracting fault zone properties from F_g observations, due primarily to an insufficient amount of lateral and vertical observational coverage for FZGW tomography along major faults. Compared to the century-long history of mapping of the Earth's complex velocity structure with seismic waves, mapping of fault-zone properties, widths, depths, segmentation, heterogeneity, anisotropy, and healing after earthquakes using F_g -waves is just beginning.

Fiber Optic Distributed Strain Sensing for Seismic Applications

Thomas Reinsch¹, Philippe Jousset¹ and Charlotte M. Krawczyk^{2,1}

¹GFZ German Research Centre for Geosciences, Potsdam, Germany

²Institute for Applied Geosciences, Technical University Berlin, Berlin, Germany

Definition

Fiber optic distributed strain sensing relies on the interrogation of an optical fiber using an appropriate light source, typically a laser. When light travels through an optical fiber, it interacts with the fiber glass structure. The interaction can be elastic (Rayleigh) or inelastic (Raman or Brillouin) scattering phenomena. Among other, the scattered light can carry information about the current elongation of the optical fiber. Comparing the elongation from successive measurements, strain changes can be detected with a high temporal and spatial resolution. If a fiber optic cable is coupled to the ground, these strain changes are a measure of the ground motion and can hence be used for seismic applications.

Introduction

To determine crustal properties distribution, seismic source processes, and wave propagation mechanisms, the acquisition

of dense seismic and ground motion datasets is required (e.g., Jousset et al. 2018). Seismic and ground-motion datasets are typically acquired measuring acceleration, velocity (e.g., geophones and broadband sensors), or position (e.g., GNSS sensors) with individual sensors located in a favorable geometry. A high-resolution image of the subsurface, thereby, requires a dense spatial coverage of sensors.

In recent years, fiber optic sensor technologies have been increasingly used for seismic applications. Different acquisition strategies have been applied to measure the subsurface deformation: measurements at a single point using specially engineered fiber optic point sensors, quasi-distributed measurements along an optical fiber with an array of point sensors, or fully distributed, where deformation is detected using interaction of light with the molecular structure of the fiber itself. We will consider fully distributed technologies in the following, only.

Optical Fibers

When light is coupled into an optical fiber, it is typically guided within the core of the fiber. Optical fibers are mainly made of doped silica glass to engineer a desired refractive index. The core of a fiber is surrounded by a clad, also made of silica but with a lower refractive index. For a given angle of incidence, light propagating within the core towards this interface fulfils the condition for total reflection, is reflected back towards the core and hence confined within the fiber. If only a single mode of propagation is possible for a given wavelength, these types of fibers are called “single-mode fibers,” in contrast to “multi-mode fibers” where multiple propagation modes are possible. Single-mode fibers that are mostly used for distributed strain sensing have typical diameters for the core/clad of 8–10/125 μm , multi-mode fibers often 50 or 62.5/125 μm , respectively (Refi 1998). In order to protect the optical fiber from external forces and to preserve the fiber’s mechanical strength, a protective coating is applied (Refi 1998) with typical diameters of, e.g., 155 μm (Fig. 1).

Fiber Optic Distributed Strain Sensing for Seismic Applications, Fig. 1 Schematic of a multimode optical fiber. Inset: Scanning electron microscopy image of a multimode fiber

Depending on the application, mostly polymer (e.g., acrylate) coatings materials are used. For high-temperature applications, also metal coatings (e.g., aluminium, copper, or gold) are manufactured.

Cable Coupling

To assess the coupling between the optical fiber and the subsurface, a detailed evaluation of the cable structure and the cable installation procedure is required. Typically, optical fibers are embedded in a multilayer cable structure. Within such cables, the optical fibers are embedded in a tube surrounded by a gel-type filling compound (Refi 1998). Depending on the application, the tube material is either some hard plastic or metal. In addition, to the tube with the optical fiber, at least some strength members (e.g., steel wires or Kevlar fibers) are used to give the cable the required strength. For most cables, a polymer jacket is extruded on the cable. For long wavelength and small amplitude signals, typical for seismic applications, the cable structure can be assumed to behave fully elastic. In addition, friction at the surface of the cable is generally sufficient for a good strain transfer between optical fiber and the ground for seismic frequencies (Reinsch et al. 2017). However, if short wavelength or high amplitudes are of interest, a tight cable design is required and the transfer function for the strain transfer to the optical fiber should be studied in detail.

Determination of Strain Changes Along Optical Fiber

When light travels through an optical fiber, part of the light is scattered at random inhomogeneities within the optical fiber. While the dominant scattering phenomenon is elastic Rayleigh scattering, also inelastic Raman and Brillouin scattering phenomena occur. When light is scattered within the optical fiber, a fraction of the light is captured and travels back into the direction of the incident light. For an incident light pulse and an appropriate receiver set-up, the two-way travel-time of the light can be used to locate the scattering position along the fiber. This method is called optical time domain reflectometry (OTDR) (Barnoski and Jensen 1976; Personick 1977) and was introduced as a measure for the signal attenuation along optical fibers and fiber optic installation ▶ “Fiber-Optic Sensing in Geophysics, Temperature Measurements”. Based on the OTDR technology, several measurement principles capable of quantifying distributed dynamic strain changes along the entire optical fiber have been developed (e.g., Masoudi and Newson 2016, and references therein). The technology of distributed strain sensing, interrogated at seismic frequencies, is typically based on elastic Rayleigh

scattering from a coherent laser pulse and referred to as distributed vibration sensing (DVS) or distributed acoustic sensing (DAS) (Hartog et al. 2013). We will use the term DAS in the following. If a coherent laser pulse is launched into the fiber, not only the amplitude but also the phase of the back-scattered photons can be analyzed (Φ -OTDR). The phase of the backscattered photons is sensitive to both, temperature and strain changes along the optical fiber. As the temporal scale of temperature changes is typically long compared to strain changes induced by seismic waves, the measured signal can be attributed to the detection of ground motion. To detect dynamic phase changes along an optical fiber, for example, an imbalanced Mach-Zehnder interferometer has been used (Posey et al. 2000). For any section of the fiber, the phase-difference $\Delta\Phi$ of photons scattered at both ends of that sections is linearly related to the length of this section (Masoudi and Newson 2017). When the section of the sensing fiber is unperturbed, the length and, consequently, the phase difference $\Delta\Phi$ remains unchanged. Any perturbation inducing a strain ϵ on the fiber will change that difference. Measurements, capable to resolve perturbations, in the nc-range are reported (Masoudi and Newson 2017). A fiber optic cable can hence be considered a system consisting of a large number of one component relative strain gauges. The length of these sections is typically referred to as gauge length.

DAS Versus Conventional Seismic Sensing

Conventional seismological sensors probe ground velocity or acceleration at specific locations, e.g., point sensors. DAS sensors measure average strain along the fiber over the gauge-length (typically 10 m). At a single location, The measurement of deformation is insensitive to the direction of the incoming signal. Whether a seismic wave arrives from one side or the other towards a given interval in the optical fiber will both lead to the same deformation – contraction or extension (Frignet and Hartog 2014; Papp et al. 2017). Only by comparing neighboring traces, the spatial propagation of the incident wave can be compared and the polarity of the signal can be analyzed.

DAS is sensitive to strain changes in direction of the optical fiber, only. To overcome the limitations of a sensor array with one component channels, various cable designs have been proposed and tested to increase broadside sensitivity. One design, the “helically wound cable”, where the optical fiber is wrapped under a specific angle around a central cable member, gained special interest in literature. Kuvshinov (2015) theoretically describes such a helically wound cable that was extensively tested in the field by Hornman (2016). The author was able to show that the helically wound fiber is capable of detecting p-waves independent of the angle of incidence.

Fiber Optic Distributed Strain Sensing for Seismic Applications, Fig. 2 Normalized maximum amplitude with respect to wavelength for a gauge length of 10 m

The acquisition of strain or strain changes over a specified gauge length introduces a spatial filter (e.g., Dean et al. 2017). Figure 2 shows the effect of the geometric filter caused by an acquisition system with a gauge length of 10 m and an incident wave in axial direction. As the optical fiber is interrogated with a laser pulse of a given duration (i.e., pulse width = length in the optical fiber), typically a few meters of fiber are illuminated at the same time. As light is back-scattered from a larger interval, the pulse width also effects the amplitude response of the DAS system (Dean et al. 2017). Whereas algorithms in seismology typically rely on processing in the frequency domain, distributed strain sensing data allows for and requires processing in both, time and space or frequency and wavenumber.

Localization of the Sensor Position

Typically, conventional seismic point sensors are localized using accurate GPS measurements. For fully distributed fiber optic sensors, this concept has to be modified. Distributed fiber optic data is recorded as a function of the optical fiber length. Although the position of the fiber optic cable is known with a high accuracy, the position of individual traces along the optical fiber can differ from a simple correlation of the distance between the readout unit and individual positions along the fiber optic cable. Aspects to consider are:

- Fiber optic cables are never installed without an excess length at the termination at both ends. For splicing fibers, sufficient excess cable length is required to pull the cable to a good working environment. This is especially true for connections in subsurface installations, where the cable is pulled into a tent or a splicing van. In order to have a sufficient safety margin to allow for splicing connectors

to the optical fibers, at least a couple of meters of optical fibers are placed in so-called splice closures. Such is also true if there is a splice somewhere along the fiber optic cable to be measured (Refi 1998).

- If the connector at the end of the optical fiber is different from the socket, a the readout-unit, an additional patch cord or cross-over cable of a few meters has to be used.
- The distance of individual traces along an optical cable is determined by the two-way travel time of light from a readout unit multiplied by the speed of light in the optical fiber. The speed of light can be expressed in terms of the refractive index of the glass. A slight inaccuracy in the refractive index determination can easily add up to a positioning error of several meters for a measured length of a few kilometers.
- Typical fiber optic cables are produced with an excess length of optical fiber. The excess length is designed such that even when stretching the cable under load, the fiber is not stretched more than 0.33% (Refi 1998). Depending on the application, this design condition typically results in an excess length of a few per-mill.

Due to the different elements detailed above, the measured length between individual position along the optical fiber, determined by the time of flight for the light, does not necessarily correspond to a geographical distance in a given reference coordinate system. In order to associate the geographical position of any measured trace along the cable, signal sources with a known position and a known characteristic can be used. For surface application, hammer shots can be used. In down-hole applications, tapping on the wellhead can generate a sufficient signal. Such a procedure is suitable to locate individual traces with a meters accuracy.

Selected Case Studies

Natural hazard assessment and efficient crust exploration require dense seismic observations both in time and space. Seismological techniques provide ground-motion data, whose accuracy depends on sensor characteristics and spatial distribution. Dynamic distributed strain sensing allows for a high spatial resolution that can be achieved along fiber optic installations. For downhole installations, several studies were performed to evaluate the potential of Vertical Seismic Profiling, by Rector and Mangriotis surveys. Generally, it has been shown that although fiber optic data has a lower signal to noise ratio compared to conventional borehole seismic sensors, the higher spatial resolution allows to acquire high resolution exploration results (e.g., Mestayer et al. 2011; Cox et al. 2012; Daley et al. 2013; Götz et al. 2018).

The densification of ground motion sensors, offered by the fiber optic DAS technology, not only allows for a spatially

un-aliased data but also for the detection of microseismic events, typically undetected by conventional seismic networks. Li and Zhan (2018) used template matching methods to analyze DAS data from the Brady Hot Springs geothermal field, Nevada, USA. The authors found a significant number of microseismic events below the noise level in the DAS data and could extend the local earthquake catalogue to study the correlation of microseismicity and subsurface pressure changes associated to the operation of a nearby geothermal power plant. On the same array, Wang et al. (2018) compared DAS data with ground motion data from colocated geophones. The authors compared the signal to noise ratio (SNR) from both recordings and found that the SNR of a single DAS channel is typically lower by a factor of two when compared at frequencies of a few Hertz but increases for lower frequencies. In recent years, it has been shown that dynamic strain determination is also possible with conventional fiber-optic cables deployed for telecommunication. Lindsey et al. (2017) showed that it is possible to monitor ground motion from regional seismic and teleseismic events using telecommunication fiber-optic cables. Dou et al. (2017) and Ajo-Franklin et al. (2019) recorded ambient noise using DAS and showed the potential of DAS data for time-lapse imaging of shear wave velocity structures. Dou et al. (2017) were able to achieve a repeatability of 2% in the model domain for the uppermost 20 m. Jousset et al. (2018) acquired high resolution spatially un-aliased broadband strain data associated to seismic signals from natural and man-made sources on Reykjanes Peninsula, Iceland. Structural features, such as normal faults and volcanic dykes were identified in the Reykjanes Oblique Rift with unprecedented resolution (4-m data spacing) along a 15 km fiber-optic cable layout. Conventional seismometer recordings, acquired simultaneously, validated the spectral amplitude of the DAS response between 0.1 and 100 Hz bandwidth. Jousset et al. (2018) suggested that the networks of fiber-optic telecommunication lines worldwide could be used as seismometers opening a new window for seismic hazard assessment and exploration.

More and more applications in various fields of Earth Sciences are emerging, e.g., measurements in marine environment, taking advantage of the network of optical cables (e.g., Lindsey et al. 2019; Marra et al. 2018; Sladen et al. 2019; Williams et al. 2019; Jousset 2019). First measurements were also performed on active volcanoes and cities build on the flanks of active volcanoes (Jousset et al. 2019) using infrastructure of temporary or permanent monitoring networks (Contrafatto et al. 2019).

Summary and Conclusions

Fiber optic distributed strain sensing has shown to be capable to complement conventional ground motion sensors, such as,

e.g., geophones or broad band stations. Individual fiber optic sensor positions have a lower signal to noise ratio compared to conventional sensors. Furthermore, fiber optic sensors are typically only sensitive in the direction of an optical fiber. The high densification of distributed sensor positions, however, offers the opportunity for unprecedented subsurface imaging. Due to the continuous improvement of broadband internet access, fiber optic infrastructure is pervasive in urban environments. Also, numerous marine cables crossing all major oceans and connecting almost all parts of the world are already deployed. In addition to the installation of dedicated sensing fibers, utilizing such an infrastructure for distributed sensing opens up an opportunity for a plethora of novel applications. Dense data acquisition will help to further unravel earth's structure and dynamics.

Definition

Temperature measurements for geophysical applications using fiber-optic methods

Temperature: formation temperature, borehole temperature

Introduction

Temperature measurement has a very long history in geophysics where it has been used for many different applications employing various sensing methods. With most relevance for solid earth geophysics, the direct measurement of temperature in boreholes is considered here.

Within the past decades, continuous developments in fiber-optic sensing have resulted in new sensor types, with certain advantages over conventional methods for temperature measurements. For measurements in boreholes, mainly electronic sensors have previously been used, either incorporated in downhole tools for wireline logging, or deployed as thermistor chains.

There has been a rapid evolution of fiber-optic sensing methods since the 1990s. Apart from temperature, several other physical quantities like pressure or strain and chemical parameters can be measured.

Distributed temperature sensing (DTS) is probably by far the most frequently applied fiber-optic technology. The initial development was driven by the energy sector, for monitoring of power cables and transformers in the electricity transmission networks. In earth sciences, Hurtig et al. (1993) carried out early tests of applying DTS for temperature measurements in boreholes. Wisian et al. (1998) compare DTS to other conventional temperature logging methods. Since the year 2000, there is a strong increase in number of scientific publications, mainly in the oil and gas sector, with a steady growth until now.

Within this entry, we first explain the design of the most common types of optical fibers. We then give an overview of different sensor types and configurations, followed by a description of the most important methods for temperature sensing. Particular emphasis is on Raman DTS, which is the method most frequently applied. Next, we describe how optical fibers are deployed in boreholes. The final section then

gives an overview of the applications of fiber-optic temperature measurements in solid Earth geophysics and related disciplines.

Optical Fibers

Optical fibers for downhole use usually have cylindrical cross-section with several co-axial layers. The light mainly propagates within the core of the fiber, which is surrounded by an outer layer referred to as the “cladding.” Both core and cladding are primarily made of silica glass (SiO_2). In order for a fiber to act as a waveguide, the refractive index of the core is set to be greater than that of the cladding. This is typically achieved by adding small amounts of other elements referred to as “dopants” either to the core or the cladding region of the glass to adjust the refractive index accordingly.

Within the fiber core, the light can follow different paths at different angles with respect to the fiber axis, which are referred to as propagation “modes.” Standard single-mode telecom fibers have a very small core diameter of typically 8–10 μm , and only support one propagation mode. Multi-mode fibers have larger cores with typical diameters of 50 μm . Due to their different path lengths, different modes travel at different velocities along the fiber, which results in a spreading of the light pulse, which is also known as modal dispersion. In a graded-index fiber, the differences in mode velocities are reduced by gradually changing the refractive index from the core to the cladding, resulting in much reduced dispersion.

The outer layer, or coating, of an optical fiber serves to improve the mechanical characteristics of the fiber and protects it from undesirable environmental influences. The coating material is selected according to the temperature and chemical substances the fiber will be exposed to, and can be made of a combination of materials, including plastic (e.g., acrylate, silicone, polyimide) or metals (e.g., aluminum, copper, gold). The coating material primarily determines the temperature tolerance of optical fibers.

Sensor Configurations, Sensing Methods

The field of optical fiber sensors falls into two broad categories, namely point sensors and distributed sensors. A point temperature sensor can quantify the temperature at a discrete, predetermined point. The role of the optical fiber in such a sensor is to transmit the probe light to the point of interest where the sensing node is installed and carry the altered light back to the interrogator for analysis.

The architecture of some of the point sensors allows them to be daisy chained, or multiplexed, to form an array. Such a

sensor array, which is also known as a “quasi-distributed” sensor, can be interrogated by a single device, hence significantly reducing the per-node cost of such sensing systems.

Point Sensors, Sensor Arrays

A wide range of optical phenomena have been employed to realize single point optical fiber temperature sensors. Temperature sensors based on optical microfibers, fiber Bragg gratings (FBG), and optical interferometers are among the optical probes that have been used for thermometry (Yin et al. 2008). Despite their high sensitivity and wide sensing range, not all of these probes can be ruggedized for field deployment purposes. For geophysical applications, only ruggedized FBG-based sensors have been adopted in practice. Besides

temperature sensing, FBG sensors are also used for strain and pressure measurement.

An FBG is a reflective structure in an optical fiber which is formed by a periodic variation in the refractive index (RI) of the fiber core (Fig. 1a). The pitch of this periodic structure dictates the wavelength at which the FBG reflects light. The relationship between the pitch and the reflected wavelength is given by

$$\lambda_B = 2n_{eff}\Lambda \quad (1)$$

where λ_B is the Bragg reflection wavelength, n_{eff} is the effective RI of the fiber, and Λ is the pitch of the periodic structure. Any increase in temperature of the fiber results in

Fiber-Optic Sensing in Geophysics, Temperature Measurements, Fig. 1 Fiber Bragg grating (FBG) temperature sensors. (a) FBG structure and its response to broadband incident light. (b) An FBG sensing array with three sensing nodes that reflect the light at three different wavelengths

Fiber-Optic Sensing in Geophysics, Temperature Measurements, Fig. 2 Light scattering mechanisms and their spectra in silica fiber for 1550 nm incident light. Different curves show the evolution of the backscattered light spectrum as a function of temperature

a thermal expansion that changes the pitch length and the RI. The temperature sensitivity of the Bragg wavelength is given by

$$\Delta\lambda_B = \lambda_B(\alpha + \beta) \Delta T \quad (2)$$

where α and β are the thermal expansion and thermo-optic coefficients of the fiber. This equation links the shift in the Bragg wavelength to a change in temperature based on two fixed coefficients. Commercial downhole FBG-based gauges with temperature accuracy around ± 0.1 K over a temperature range of 25–150 °C are available.

FBGs with different Bragg wavelengths can be fabricated and spliced together to form a sensing array also known as quasi-distributed sensor (Fig. 1b). A single broadband source can interrogate several FBGs with different Bragg wavelengths (James et al. 1996). The sensing procedure of each individual FBG in this array follows the same principle elucidated earlier. Most advanced commercial FBG interrogators can analyze up to 150 sensing points along 1 km long optical fiber.

GaAs-based optical fiber sensors have also been developed for temperature measurement in harsh environmental conditions. But their use, so far, has been limited to process monitoring, medical applications, and high radiation environments. The main advantage of GaAs-based optical fiber thermometers over their FBG counterparts is their insensitivity to external strains.

Distributed Sensing

The operation of distributed optical fiber temperature sensors is markedly different from that of single point sensors. In a *distributed temperature sensor* (DTS), the optical fiber is used both as a medium to carry the light and as a sensing element. A DTS system relies on the light scattering inside the fiber to

spatially resolve the temperature along tens of kilometers of optical fiber.

There are three light scattering mechanisms in an optical fiber: Rayleigh, Brillouin, and Raman (Fig. 2). Although all three scattering processes are temperature dependent, only Brillouin and Raman scattering have been employed for DTS. The effect of an increase in temperature on the spectrum of Brillouin and Raman scattering is shown in Fig. 2. DTS systems map the temperature distribution along an optical fiber by measuring and analyzing the spectrum of the backscattered light at each point on the fiber.

Interrogation Techniques

To spatially resolve the temperature distribution along an optical fiber, the backscattered light from each individual section of that fiber needs to be captured first. The most commonly used interrogation technique employed for analysis of light scattering in an optical fiber is known as *optical time domain reflectometry* (OTDR). In this technique, a laser source is modulated to form an optical pulse (Fig. 3a). As the probe pulse propagates down the fiber, a small fraction of the light is scattered in all directions through the three mechanisms mentioned earlier. The portion of the scattered light which is recaptured and guided back toward the front-end of the fiber is called the backscattered light. The time it takes for the backscattered light from a point on the fiber to reach the front-end of the fiber depends on the distance between the two points. Therefore, the backscattered light from the sensing fiber appears as a time-domain trace known as OTDR trace where each point on the trace corresponds to the backscattered light from an interval on the sensing fiber. Since the backscattered light from the fiber has all three scattering components (i.e., Rayleigh, Brillouin, and Raman), an optical filter is added before the photodiode to transmit the desired component of the backscattered light and block the rest.

Fiber-Optic Sensing in Geophysics, Temperature Measurements, Fig. 3 (a) Schematic diagram of optical time domain reflectometry (OTDR) system and its typical OTDR trace, (b) building blocks of a

distributed temperature sensor (DTS) based on OTDR interrogation technique. The diagram shows the effect of temperature changes on the OTDR trace

Other interrogation techniques such as *optical frequency domain reflectometry* (OFDR) have also been used to devise DTS systems (Hartog 2017).

DTS Based on Raman Scattering

Raman-based OTDR systems are the most widely used and well-established technique for distributed temperature sensing. The simplicity of an OTDR setup combined with inherent temperature sensitivity of Raman scattering makes Raman-based OTDR systems the best candidate for distributed temperature measurement. The most common technique used to measure the temperature is by analyzing the intensity of Raman Stokes and anti-Stokes signals. As illustrated in Fig. 2, for a fixed temperature change, the variation in the intensity of Raman anti-Stokes is much more significant compared to that of Raman Stokes. Therefore, the temperature of the fiber can be determined from the ratio R between the intensity of the Raman anti-Stokes, I_{AS} , and the Raman Stokes, I_S , components (Hartog 2017):

$$R(T) = \frac{I_{AS}(T)}{I_S(T)} = \frac{K_{AS}}{K_S} \left(\frac{\lambda_S}{\lambda_{AS}} \right)^4 \exp \left(-\frac{S_{LE}}{T} \right) \quad (3)$$

where K is the scattering coefficient, λ the wavelength, S and AS refers to Raman Stokes and anti-Stokes, respectively, S_{LE}

coefficient defines the temperature sensitivity of the system, and T is the temperature in Kelvin. The S_{LE} coefficient can be determined by calibration, where the Raman ratio is measured at known temperatures.

Figure 3b shows a typical block diagram of a Raman-based DTS system based on OTDR interrogation technique. In this DTS embodiment, an optical filter is used to separate the Raman Stokes and anti-Stokes backscattered light to form two OTDR traces, one for Stokes Raman and the other for anti-Stokes Raman. By dividing the two OTDR traces and compensating for wavelength-dependent, or differential, attenuation, the temperature distribution along the fiber can be determined with the help of Eq. (3). DTS systems use a stretch of fiber at a known temperature, which is referred to as the reference fiber or reference coil, in order to eliminate the influence of variable parameters within the interrogator.

As mentioned earlier, Brillouin scattering can also be used for temperature measurement. However, unlike Raman scattering, which is only sensitive to temperature, Brillouin scattering is sensitive to both temperature and strain. Therefore, Raman-based DTSs have an advantage in applications where only the temperature needs to be mapped. However, in studies where both the strain and temperature need to be measured, distributed sensing systems based on Brillouin scattering should be employed.

Fiber-Optic Sensing in Geophysics, Temperature Measurements,

Fig. 4 Distributed temperature measurement with differential attenuation compensation based on (a) special fiber configuration, and (b) dual-wavelength measurement

Implementation

As discussed in the previous section, the temperature at any point on the fiber is proportional to the ratio between the intensity of the anti-Stokes and Stokes Raman backscattered light. The intensity of the Raman backscattered light depends on both the Raman scattering coefficients as well as the fiber attenuation at the Raman anti-Stokes (λ_{AS}) and Stokes (λ_S) bands. In an ideal optical fiber and under ideal environmental conditions, the differential attenuation between the two Raman bands is fixed, which makes it easy to eliminate the effect of fiber attenuation on the Raman backscattered light and, subsequently, the temperature measurement. In reality, the differential attenuation along the fiber can be variable. Under harsh environmental conditions such as high temperature and excessive pressure, the fiber attenuation can be altered through a process known as hydrogen ingress or hydrogen darkening (see section below). A distributed temperature measurement along an optical fiber in which the effect of differential attenuation has not been compensated for can result in a significant disparity between the actual and measured temperature.

Two techniques have been devised to eliminate the effect of differential attenuation on temperature measurements, one based on special fiber configuration and the other based on multi-wavelength measurement (Hartog 2017).

One approach to eliminate the effect of optical fiber attenuation is to arrange the sensing fiber in a loop configuration as shown in Fig. 4a. In both configurations, the optical fiber is arranged in such a way to provide two separate Raman scattering read-outs at any given section. It is shown that the two read-outs at a given section can be combined to compensate for any signal attenuation due to fiber loss and to provide an accurate temperature measurement.

The main disadvantage of this technique is the feasibility of such fiber arrangements. In many cases, the access to both ends of the fiber is not feasible. The other issue with this compensation approach is its vulnerability to fiber breakage. The double-ended method ceases to work if the fiber is damaged at any point along the loop.

The other compensation method relies on measuring the fiber attenuation at the anti-Stokes Raman band to adjust the intensity of the Raman backscattered trace. This multi-

wavelength measurement procedure is illustrated in Fig. 4b. At the first step, a probe pulse (λ_P) is launched into the fiber to obtain the OTDR trace at the anti-Stokes Raman band. To assess the fiber attenuation, a second probe pulse at the anti-Stokes Raman band (λ_{AS}) is launched into the fiber and the Rayleigh backscattered light is collected. By analyzing the intensity of the Raman backscattered light and comparing it with the fiber loss measurement, an accurate temperature measurement can be achieved.

Temperature Accuracy and Resolution

The measurement accuracy, that is, the difference between measured and true absolute temperature, or systematic error, of a Raman DTS interrogator depends on the calibration and stability of the system, as well as how well differential attenuation has been compensated for. For example, Henninges et al. (2005) have reported an accuracy of ± 0.3 °C for a calibrated Raman DTS system using double-ended processing, both under field and laboratory conditions, while Voigt et al. (2011) observed a temporal drift of ± 2 °C over a period of 5 days attributed to unstable optical connectors using single-ended processing.

The temperature resolution, that is, the repeatability of the measurement, or random error, depends on the following parameters:

- Integration time, that is, length of time interval over which a measurement is averaged
- Length and attenuation of the sensing fiber
- Noise figure of the components used in the interrogator

The temperature resolution is proportional to the inverse of the square root of integration time, and example numbers achievable with a current Raman DTS instrument are listed in Table 1. While the fiber length and signal attenuation are features characteristic to an individual DTS installation, the integration time can be adjusted to the conditions and requirements of an individual measurement campaign.

Hydrogen Darkening

Under influence of hydrogen, rapid degradation of the properties of optical fibers has been observed (Smithpeter et al. 1999). Additional optical loss due to absorption is caused by diffusion of hydrogen into interstitial sites in the silica lattice,

and chemical reaction with the glass constituents resulting in hydroxyl (OH) formation, which is amplified by dopants such as germanium or phosphorus (Williams et al. 2000). Appropriate shielding is especially difficult at elevated temperatures, as the diffusion of hydrogen through steel increases at temperatures >150 °C. The interrogation approaches described above for Raman-based DTS are only effective at low levels of hydrogen ingress. Other measures to avoid hydrogen darkening include modification of the fiber dopants, use of hermetic coatings with a carbon layer, design of sensor cables including hydrogen barriers, and operation of the interrogator at wavelengths that are less affected by hydroxyl absorption.

Sensor Cables, Deployment Methods

In order for the fiber to maintain its optical transmission properties during deployment, that is, during installation and operation, it needs to be protected against external influences like mechanical stress or ingress of hydrogen. The protective jacketing or armor must be able to tolerate the harsh environmental conditions which can prevail in boreholes, like high temperature and pressure, corrosive fluids, as well as the occurring mechanical loads.

For temperature sensing applications, the fibers are usually inserted into a thin stainless steel tube with about 2 mm diameter, which is typically filled with a water-blocking gel. This is a standard technology for optical fiber cables which are also used in other application fields, for example, in the telecom sector. Depending on the individual deployment conditions, an appropriate sensor cable design has to be employed. Sometimes, a hybrid design is used, that is, with optical fibers and electrical conductors, for simultaneous operation of different fiber-optic and electronic sensors in parallel. For boreholes, basically two different deployment methods described in the following are used in practice.

Permanent Installation

Here ruggedized cables, often with a second steel tube, and an outer plastic jacketing are used. Such cables can be strapped to production tubing using special protector clamps at the tubing joints, which is standard industry practice in oil and gas wells. Cables can also be installed behind casing and cemented (e.g., Henninges et al. 2005). This has advantages for the measurement due to the proximity of the sensor cable to the formation, but it is also more challenging to avoid damage during installation or perforation, or potential leakage pathways in the cement.

Another method is the use of fibers which are pumped into hydraulic control lines (e.g., Brown et al. 2000), which are typically 0.64 cm in diameter, and can be up to several

Fiber-Optic Sensing in Geophysics, Temperature Measurements, Table 1 Examples for temperature resolution of a Raman DTS measurement, as a function of fiber length and integration time. (After Voigt et al. 2011)

Fiber length (m)	RMS error (°C), 60 s integration time	RMS error (°C), 10 min integration time
1000	0.05	0.02
4000	0.28	0.04

kilometers in length. As a great advantage, the fiber can be replaced in case of fiber degradation.

Temporary/Retrievable Installation

A fiber-optic sensor cable can also be lowered down inside a well, similar to a conventional wireline operation. This method can be applied in already existing wells, or in cases where the well design makes a permanent installation to the desired target depth difficult. When using distributed sensing methods, the entire profile along the installation interval can be monitored simultaneously once the sensor cable is in place. This is a great advantage over conventional wireline techniques, which require that the logging tool is moved along the section of interest with a defined speed.

For this purpose, optical fibers can be deployed using a slickline cable with a design similar to the one for permanent installations described above, as well as using coiled tubing, or inside a fiberglass rod. Here nevertheless only data acquired on the optical fibers, eventually together with data from the logging winch like cable tension and cable speed during running into the hole, can be recorded.

Henninges et al. (2011) developed a hybrid borehole measurement system, with an armored wireline cable containing both electrical conductors and optical fibers. This allows for parallel deployment of fiber-optic sensors and electric down-hole tools. In addition, data like gamma-ray or casing-collar locator logs can be simultaneously recorded, allowing for proper depth correlation. With the advent of distributed acoustic sensing (DAS), there is increasing interest for development of such hybrid wireline cables (e.g., Hartog et al. 2014).

Applications, Methods of Evaluation

Passive Monitoring

Formation Temperatures, Heat Flow Studies

One of the classical applications of borehole temperature measurements is the determination of formation temperatures, for example, for heat flow studies. The prerequisite for this is that the well is in thermal equilibrium with the surrounding formation. It is important to consider that this may not always be the case, and that the well temperature can be influenced from the movement of fluids within the borehole, for example, due to fluid circulation during drilling.

Henninges et al. (2005) performed repeated DTS measurements in three wells to a depth of 1200 m over several years and monitored the decay of the thermal disturbance after drilling in order to determine the undisturbed formation temperatures (Fig. 5). From the geothermal gradients, profiles of the in situ thermal conductivities were derived. The use of permanently installed sensor cables enabled to perform

Fiber-Optic Sensing in Geophysics, Temperature Measurements, Fig. 5 DTS temperature profiles for successive times after completion (t_s) of the Mallik 3L-38 well. Left: well sketch showing completion and position of DTS sensor cable. Right: geological sequence boundaries. IBPF: base of ice-bearing permafrost. (After Henninges et al. (2005))

measurements even after abandonment, when the wells were not accessible anymore for wireline equipment.

Flow Profiling

The temperature profile of wells can also be used to derive estimates of the flow profile during production or injection. Conventionally, production logging is performed using downhole tools equipped with impeller flowmeters and differential manometers which is operationally expensive. Evaluation methods using temperature are based on models for the heat transfer inside and around the wellbore, for which analytical approximations have been developed by Ramey (1962). The temperature of the produced fluids depends on the geothermal temperature and the thermal properties as well as the flowing velocities of the borehole fluids. In addition, thermal effects caused by the pressure drop between the formation and the well (Joule-Thomson effect) have to be accounted for.

The method has been greatly facilitated by availability of DTS because of the simplicity of the measurement process.

Brown et al. (2000) derived flow profiles from DTS temperature data in extended-reach deviated oil wells, with completions where conventional production logging would not have been possible. Evaluation was performed in conjunction with other production data using a wellbore simulator, as solutions are not always unique using temperature alone.

Flow profiling using temperature is also of interest for geothermal wells. Henninges et al. (2012) performed DTS measurements during a production test in a 4300 m deep geothermal well using a hybrid wireline cable (Fig. 6). Using this data, they were able to derive information on temporal variations of flow from individual reservoir zones characterizing the hydraulic behavior of this enhanced geothermal system (Blöcher et al. 2016).

A different method is based on observing the temperature recovery after shut-in of injection into a well (warm-back). Using this technique, permeable regions that have accepted larger fluid volumes can be identified through differences in the cooling effect and the duration of the recovery process (Witterholt and Tixier 1972).

Well Cementing and Well Treatments

The DTS method has also been successfully applied for on-line monitoring of well cementing and well treatments like hydraulic fracturing or thermal stimulation. Hartog (2017) contains an extensive review of different applications and related publications, primarily from the oil and gas sector. More recently, the DTS method has also increasingly been used in combination with DAS, which enables to derive additional information on flow inside the well from noise generated at injection or production zones, or changes of the propagation of acoustic waves along the well.

Another important application for DTS is the monitoring of steam injection during heavy oil production. Here process temperatures of 220–270 °C are being used, and DTS is applied to understand where the formation has been heated and in order to maintain the desired temperatures, as well as to avoid steam breakthrough at the producer well. The high temperatures create the risk of fiber degradation by hydrogen darkening, which requires appropriate mitigation measures to be applied (see section “Distributed Sensing”).

Fiber-Optic Sensing in Geophysics, Temperature Measurements, Fig. 6 DTS temperature data and gamma ray logs (GR) during a production test in the GrSk4 well. Acquisition times of DTS profiles

not displayed in log header: light blue 12:29, gold: 13:02, orange: 13:28. (After Henninges et al. (2012))

In practice, special interrogation techniques to compensate for additional loss have been applied, or the fibers are installed in hydraulic control lines, which enable to replace them after degradation.

High-Temperature Applications

In order to avoid the adverse effects of hydrogen ingress in high temperature and high pressure environments, either fibers with metal coating or fibers with hermetic coatings including a carbon layer have been proposed. Until now, metal-coated fibers exhibit high attenuation, especially at low temperatures (Reinsch and Henningses 2010), which limits their use to short sensing ranges. Hermetic coating fibers have been tested in geothermal wells in the United States, where they maintained their optical properties over 7 months at 171–182 °C, but rapidly failed in another well when exposed to temperatures up to 243 °C (Smithpeter et al. 1999). During a field test in a high-temperature geothermal well in Iceland, Reinsch et al. (2013) have successfully deployed fibers with hermetic coating at temperatures up to 230 °C over a period of 14 days, but reported different signs of degradation occurring after exposure to temperatures above 300 °C.

Another approach is the use of pure-silica core (PSC) fibers without dopants in the fiber core, which makes them less susceptible to hydrogen darkening. Kaura and Sierra (2008) successfully tested single mode PSC fibers for DTS monitoring during a 20-month trial at temperatures up to 250 °C in a steam injection well. Nevertheless, single-mode DTS systems have lower spatial and temperature resolution due to lower signal intensity compared to multimode systems. Step-index PSC fibers are not suitable for multimode DTS systems due to pulse dispersion, which degrades spatial resolution.

A third approach has been used by Ikeda (2003), who performed DTS measurements in a geothermal well in Japan at temperatures of 275 °C for 43 h of continuous operation, while flushing the tube through which fiber was deployed with nitrogen, in order to avoid degradation due to hydrogen ingress.

Active Methods

Fluid Logging, Thermal Tracer/Dilution Techniques

Flow profiling using temperature requires a measurable difference between the temperatures of the borehole and the surrounding formation. In situations with small temperature differences (e.g., low geothermal gradient along the borehole, closely spaced flow zones, horizontal wells, low flow rates and fluid velocities) the temperature difference between the fluids can be enhanced by induction of a temperature change within the well. Information about the flow along the well is derived from mixing models and by tracking the movement of

temperature features, which is similar to earlier established methods using solute tracers or fluid electrical conductivity logging.

The desired change in temperature inside the well can be induced by local fluid injection through tubing (Hurtig et al. 1994; Leaf et al. 2012) or a downhole electrical heat source (Read et al. 2015). Such methods have mainly been applied in shallow groundwater wells at depths up to 100 m until now, primarily within the context of detecting flow in fractured rock masses.

A special challenge is that fast measurements with high precision are needed. The required resolution might in some cases be difficult to achieve with the typical performance of DTS instruments.

Heat-Pulse Method

This method is used to determine in situ thermal conductivities of the formation and to derive information about heat advection and fluid flow along boreholes. It is based on the well-known theory of heat conduction along a constantly heated line source (Carslaw and Jaeger 1959), and has originally been developed in hydraulic engineering for leak detection along surface sealings and dams. The borehole is heated along its axis using electrical conductors as a controlled heat source and temperature changes are monitored with DTS.

Freifeld et al. (2008) performed an experiment in a 400 m deep borehole, which was heated for 64 h using a heating power of about 20 W/m. Thermal conductivities were determined with 1 m resolution by numerical inversion of the temperature data recorded during the 58-h cooling phase after heating. Prevedel et al. (2014) performed similar measurements along a well to a depth of 690 m. They further extended the method to investigate the properties of both the completion of the well and the surrounding rock formation by evaluating early- and late-time data of the heating and cooling phases.

The method is also used in shallow geothermal wells, where it is referred to as enhanced geothermal response test (EGRT). Lehr and Sass (2014) determined profiles of thermal conductivity along a 400 m borehole heat exchanger, and identified zones with heat convection caused by fluid flow inside the formation around the well.

Another application of this method has been for distributed measurements of soil water content at meter to kilometer scales (Sayde et al. 2010).

Other Applications in Related Disciplines

The DTS method has also increasingly been used for measurements at surface, especially in surface water bodies. Selker et al. (2006) reviewed the applications of temperature mapping in hydrological sciences, where, for example, dynamic processes in lakes and rivers can be investigated using DTS measurements. As one example, they

measured the temperature distribution along a 4 km telecom cable at the bottom of Lake Geneva between France and Switzerland.

Another application is the detection of heat discharges associated with fluid emissions at the sea floor for volcano monitoring. Carlino et al. (2016) installed a 2400 m long cable at the Campi Flegrei caldera in Southern Italy, extending from the shore into the sea to a maximum water depth of about 80 m. As for the previous example, the measurements were performed using the BOTDA method (stimulated Brillouin scattering) under the assumption that the fiber within the sensor cable was not subjected to strain and the measured effects could be related to changes in temperature only.

Surface measurements using optical fibers of telecommunication and data transmission cables have great potential for further applications in science and engineering since large networks of such cables already exist worldwide both in on- and offshore regions (You 2010).

Summary

Fiber-optic sensing has opened up new possibilities for geophysical measurements with a broad range of applications.

The optical fiber transmits the signal and can also act as the sensing element. There are no electronic parts required down-hole. Some of the resulting advantages of fiber-optic sensors compared to conventional electronic sensors are:

- Ruggedness
- Flexibility
- High temperature tolerance
- Ease of deployment
- Immunity to electromagnetic interference

The core of an optical fiber guides the optical waves and is made of silica glass. The coating layer protects the fiber from harmful influences and is made of plastic materials or metals, which primarily determine the temperature tolerance of the optical fiber. Depending on the sensing method, different types of fibers are used.

Fiber Bragg grating (FBG) sensors, which are also used for measurement of strain and pressure, have mainly been adopted as point sensors. Several 10s of these sensors can be interrogated on a single fiber through wavelength multiplexing interrogation technique.

Distributed temperature sensing (DTS) methods enable sampling with high spatial and temporal resolution over long distances of up to tens of kilometers in length. They rely on different light scattering mechanisms within the optical fiber. Most systems are based on the optical time domain reflectometry (OTDR) technique. Here the backscattered light

is captured as a function of time, and the position along the fiber is determined from the travel time of the signal.

DTS systems based on Raman scattering are used most often. Temperature is determined from the ratio of the back-scattered light at two distinct wavelengths. Other wavelength-dependent effects (differential attenuation) need to be avoided or adequately compensated. One of such effects is hydrogen darkening, which is caused by diffusion of hydrogen into the fiber at elevated temperatures. The accuracy of the measured temperature depends on the calibration and stability of the DTS system. The achievable resolution depends on the signal attenuation, and scales with the inverse of the square root of integration time.

Sensor cables used for deployment under harsh conditions of a borehole environment have to be designed to protect the optical fibers against mechanical stress and hydrogen ingress. The optical fiber is usually inserted into a thin stainless steel tube and further elements for reinforcement and protection are added, according to the deployment conditions. Hybrid cable designs with additional electrical conductors also exist.

For permanent installations, ruggedized cables are used which are deployed along tubing, or behind casing. Another method is to pump the fiber into a capillary tubing. This enables to replace the fiber in case it is damaged or degraded. Temporary or retrievable installations are either performed similar to a slickline operation, using a coiled tubing, or hybrid wireline logging cables.

There are many applications for DTS in borehole temperature measurements, especially if transient processes involving temporal changes of temperature along extended sections of a borehole need to be studied. These can be classified in passive methods, where the (naturally) occurring temperature changes are recorded, and active methods, where an additional source of heat is introduced inside the borehole:

1. Passive monitoring

- Determination of formation temperatures, observation of the decay of drilling disturbance, for example, for heat flow studies
- Flow profiling during injection or production, warm-back monitoring, leakage detection
- Well cementing and well treatments (hydraulic fracturing, thermal stimulation)
- High temperature applications (geothermal wells, steam injection)

2. Active methods

- Fluid logging, thermal tracer/dilution techniques: determination of the flow profile along well from mixing models, or by tracking the movement of temperature features
- Heat-pulse method: determination of the in situ thermal conductivity, or zones of fluid flow and/or heat advection

Other applications in related disciplines include surface measurements, for example, in hydrology or volcano monitoring, using optical fibers of telecom cables, of which large networks are already in place worldwide.

Floating Seismographs (MERMAIDS)

Yann Hello and Guust Nolet

IRD Geoazur and Université Côte d'Azur, Sophia Antipolis, France

Definition

MERMAIDS are Lagrangian floats, drifting passively with the deep ocean current, detecting seismic waves, and recording seismograms (and possibly other data) which they transmit by satellite after coming to the surface. The name is an acronym for Mobile Earthquake Recording in Marine Areas by Independent Divers (Simons et al. 2009).

History

The need to observe the abyssal current in the oceans led John Swallow in the UK and Henry Stommel in the USA to develop submarine floats in the mid-1950s (see Riser et al. 2018, for a review). Though the early floats were equipped with a hydrophone, this was only used to track the float position by recording intermittently fired explosives from a surface vessel.

The first seismological application was by Bradner et al. (1970), who equipped a spherical aluminum float (Fig. 1) with a 3-component seismometer to record microseismic noise between 0.02 and 5 Hz at a depth of 1200 m. D'Spain and Hodgkiss (1991) used 17-inch diameter Benthos glass shell as a float to measure the background noise level in the 1–20 Hz frequency band. Nolet (1991) analyzed data from this instrument and discovered a weak signal of an earthquake of magnitude 6.8 at a depth of 26 km in the Andreanoff Islands (distance 47°) showing that floating seismographs could in principle be used to record teleseisms.

At the time, the technology was not yet advanced enough to have floats operate independently in mid-ocean. This changed with the development of autonomous sensors for oceanography such as RAFOS and SOLO floats (Riser et al. 2018 – SOLO stands for Sounding Oceanographic Lagrangian Observer, the acronym RAFOS is 'SOFAR', for SOUNd Fixing And Ranging, spelled backwards.), which can transmit a small volume of data by satellite (Argos) and be located by GPS when surfacing, thus obviating the need for tracking by a surface vessel. A modern float has a bladder that allows it to vary its volume and seek the depth where it is neutrally buoyant, since the density of seawater increases slowly with depth. A nominal cruising depth of 1500 m is a good compromise to get a good signal to noise ratio during monitoring and time needed to rise to surface in order to reduce the power consumption. Simons et al. (2009) successfully tested a

Floating Seismographs (MERMAIDS), Fig. 1 The spherical float used by Bradner et al. (1970) to record microseismic noise

hydrophone attached to a SOLO float to record a number of earthquake signals.

Adapting a RAFOS float, Hello et al. (2011) subsequently developed the first MERMAID capable of autonomously detecting earthquakes and transmitting these by satellite. The current version of the MERMAID uses a 17-inch glass sphere and was developed by OSEAN-SAS and the University of the Côte d'Azur, both located in the south France.

Technical Description

In the MERMAID, all hydraulic and electronic components are encapsulated in the glass sphere except for a bladder which adapts the float volume and controls its buoyancy in the water column (Fig. 2). Oil is pumped from an inner reservoir to the bladder outside. The piston can pump oil against a pressure up to 550 bar, equivalent to a depth of 5500 m, which forces the float to ascent to the surface from a 4000 m maximum cruising depth. To descend, the oil transfer from the bladder to the inside is controlled by valve or bypass. The float measures the pressure during its descent. It calculates its speed and activates the pump or opens the valve to maintain a speed that varies according to the distance to the desired depth. For the ascent, the float will leave its cruising depth by gradually increasing its vertical speed to a maximum to reach the surface.

Floating Seismographs

(MERMAIDS), Fig. 2 The spherical glass float used by OSEAN-SAS and the University of the Côte d'Azur in France to detect, record and transmit earthquakes by satellite communication. (Credit: OSEAN-SAS)

The MERMAID contains two circuit boards. A very low power (3,3 V/7,6 mA), acquisition board interacts with a pilot board that operates the pump. Both are powered up by lithium disposable batteries, like the rest of the system (motor, pump, Iridium modem, GPS receiver). For a battery with capacity 5 KWh, the MERMAID has an expected life time of 6 years of continuous monitoring the hydrophone signal at a depth of 1500 m, if a selection of 150 Kbytes of triggered seismogram data is transmitted every week.

Signal Discrimination

After the float descends to its drift depth, it oscillates around the level of natural buoyancy, typically 1 cycle/hour, but the pressure variations introduced by this are too little and too slow to affect seismic signals. To record acoustic signals, the MERMAID is equipped with a hydrophone that monitors the pressure in the acoustic frequency band (0.1–10 Hz). This is a useful passband for seismic P waves. The MERMAID float depth is too close to the surface to record low frequency waves (surface waves, normal modes) for which the pressure perturbation increases only slowly with depth from zero at the surface. The pressure signal is continuously analyzed by comparing energy averages over a short time window with that over a long-time window. When the STA/LTA or signal-to-noise (SNR) ratio triggers an alert, a wavelet decomposition is computed. Seismic P waves are efficiently converted to acoustic waves at the sea bottom and have a distinctive

signature characterized by the power in different wavelet scales, but converted S waves have only been observed at intermediate distance ($<20^\circ$). A measure of wavelet power, combined with the SNR, may trigger a return to the surface for transmission of the seismogram per satellite (Iridium). For specific details of the algorithm, see Sukhovich et al. (2011). If the detected signal is characterized as a P wave but rated too weak, it is recorded in a buffer to be transmitted later by Iridium. On surfacing, the major events are always transmitted first.

This signal discrimination is necessary to optimize the cost of data transmission and limit power consumption. However, continuous sampled data are stored in a circular buffer with a capacity of 6 Gbytes. Any signals missed by the algorithm can be retrieved using two-way communication by satellite, and continuous signals can be read from the buffer when the float is recovered.

A Typical Mission

A typical recording cycle comprises several stages. The first stage is the descent. The acoustic detection algorithm is activated during the second stage when it drifts at the assigned depth for a specified duration. This second stage may be cut short if the acquisition board detects a seismic signal of significant amplitude. The hydrophone data acquisition is stopped before the ascent, to avoid interference of pump noise with earthquake detection algorithm. Once at the

Floating Seismographs (MERMAIDS), Fig. 3

A Mermaid being deployed from a research vessel

surface, the float fully fills its oil bladder to gain maximum buoyancy for optimal satellite communication even in high seas.

The float uses the GPS signal to get its geographical coordinates and to calculate the internal clock drift prior to synchronizing the clock on the MERMAID acquisition card against GPS time. GPS and Iridium communication system use the same helical special antenna to receive and transmit. Two-way communication allows for a command file containing float parameters such as depth and trigger level for the next dive to be downloaded. Seismograms are transferred to the SD card of the pilot board which performs the Iridium data upload. The float drift at depth is typically 4 km/day and rarely exceeds 10 km/day, whereas drift at the surface is usually between 1 and 2 km/hr; drift measurements by repeated GPS localizations allow for an accurate extrapolation of the float position during recording at depth (Nolet et al. 2019). Voltage level, internal vacuum, and external pressure are measured and a last GPS fix for MERMAID's clock synchronization is obtained before diving again.

If a major earthquake occurs in an area covered by one or more MERMAIDS, the floats have the option to revert to "lander" mode. This means that they can be commanded go down to the ocean bottom and stay anchored, much as an ocean bottom hydrophone (OBH). They can transmit recorded aftershock data by surfacing at programmed intervals until commanded to revert to their original mission at the end of the swarm. Similarly, landers can be rapidly deployed

for this purpose as an OBH network to monitor aftershocks of a large earthquake. Continuous recordings may be recovered at the end of a rapid response campaign while transmitting identified events in quasi-real time at every surfacing.

Deploying Mermaid can be done by simply pushing it overboard from a small vessel, or using a crane or U-Frame from a research vessel (see Fig. 3). To recover a Mermaid, it can be commanded to stay at the surface and send its geographical coordinates. It can be lifted aboard by hand from a small vessel or with a snap-hook and a crane on a larger vessel.

Other Sensors

The MERMAID is a very recent addition to seismic instrumentation, but in its current version integrates functionality for oceanography, notably the option to accommodate a Sea-bird SBE 41 Conductivity Temperature Depth (CTD) sensor to measure salinity and temperature down to 4000 m depth. These data are compatible with the Argo program to monitor temperature, salinity, and abyssal currents in the oceans (Riser et al. 2018). The next development is a fully multidisciplinary Multi-MERMAID hosting multiple sensors.

Multi-MERMAID

The MERMAID board is equipped with eight channels for external sensors. For example, a high frequency hydrophone allows for the monitoring of rainfall and storms over the oceans; cracking and sliding of ice sheets and icebergs;

Floating Seismographs

(MERMAIDS), Fig. 4 The 9 MERMAIDS drift freely with the ocean current. Circles show the 580 locations where one of them successfully recorded a P wave, between May 2014 and October 2016. The grayscale denotes bathymetry in m. (Modified after Nolet et al. 2019)

tracking of whales and ecological stressors (ship and airgun noise). Sensors for bathymetric, magnetic, optical, geochemical, or biological measurements can also be added. Flexibility is obtained by allowing the data management by the MERMAID board to be programmed by the scientists. A Domain Specific Language is scheduled to be operational in 2020. The software can be updated using two-way communication by satellite.

Recent Results

Sukhovich et al. (2015) showed that a large fraction of earthquakes with magnitude >6.5 are detected by MERMAIDS (35–63%, depending on the signal to noise ratio being higher than the programmed threshold, typically 2–3). Although they are a very recent addition to seismic instrumentation, Mermaids have already contributed scientific results of significance. Sukhovich et al. (2015) recorded more than 200 events of an earthquake swarm near the Indian Ocean

triple junction that were not observed by land stations. His analysis showed the ability of Mermaids to detect nearby earthquakes with Richter scale magnitudes below 3. Nolet et al. (2019) used an array of 9 first generation MERMAIDS in the Pacific to image the plume under the Galapagos islands. This study resulted in a significant increase in image resolution in the upper mantle, due to the fact that the sensors change their position continuously, thus avoiding redundant ray paths (Fig. 4). Analysis of the images showed that the Galapagos plume carries a heat flux that is a factor of 6–7 higher than was assumed earlier on the basis of the bathymetry. Since 2019, a large network of 49 Mermaids is operating in the South Pacific in an effort to image the “superplume” beneath Tahiti (Simon 2020).

Summary

Floating seismographs have been made possible by recent advances in satellite communication, GPS miniaturization,

low power high performance electronic components, and increased battery capacities. Though limited to the recording of acoustic (P) waves in the water columns, they can cover large areas and offer a low-cost complement to OBS deployments. They bring detailed resolution to seismic tomography and the option of a fast response to monitor aftershocks or seismic swarms.

Definition

Fractals define a statistical distribution that is self-similar across different scales (scale-free/scale-invariance) characterized by a power-law with no characteristic length scale. Mathematically, they represent a class of non-linear system of equations with a self-similar solution, which can be modelled by using a recursive algorithm.

Scaling leads to a power-law relationship between the scale and the corresponding measure. It can be expressed as $T[f(x)] = f(\lambda x) = \lambda^n f(x)$, where T is scaling transform, x the scale variable, $f(x)$ the function of x , λ the scale factor, n the scaling coefficient.

A 1-D profile $z(x)$ is self-affine if it is statistically similar under scaling transformation $(x, z) \rightarrow (\lambda x, \lambda^H z)$, where λ is scale factor and H the Hurst exponent or roughness index ($0 < H < 1$). A self-affine profile is self-similar for $H = 1.0$, meaning that it is statistically identical with transformation $(x, z) \rightarrow (\lambda x, \lambda z)$. Therefore, a scaled portion of a self-similar profile appears statistically identical to the whole if the same scale factor is applied in both x and z directions, which for a self-affine case requires different scale factors depending on direction. Self-affine fractals/scaling are band-limited with smooth cut-offs.

Introduction

Heterogeneity exists in earth on scales from centimeters to hundreds of kilometers characterized by the scaling laws for different scale ranges with the crossovers separating them. Models explaining them are scale dependent; i.e., a single model cannot characterize the heterogeneity over the whole range, which requires going beyond self-similarity, i.e., multi-fractality. Scale-affine, band-limited fractal scaling, a special case of multi-fractality, can properly explain observations with local transient features characterized by crossovers.

In this chapter, we define fundamental notions of both the self-affine and self-similar fractal scalings, and their application in seismology. For the application, we present statistical treatment of distributed heterogeneities and their influence on rupture and seismic wave propagation and scattering, and finally suggest ways to reliably interpret observed scaling relations.

Fractal scaling implies invariance with respect to the two fundamental scaling symmetries of nature such as dilation (change in unit of length $r \rightarrow \lambda r$; λ the scale factor), and translation (change in the origin of coordinate system $r \rightarrow r + b$, b the constant). They satisfy, both in time or frequency domain, the power-law form of any frequency-size distribution $F(s) \propto s^{-\alpha}$ (s is scale parameter, and α scaling exponent) that is valid for a large, at least for one order of the s values.

In a self-similar set S of N non-overlapping subsets, each subset of S is congruent to λS ($0 < \lambda < 1$), meaning that the whole set is composed of N copies of itself after scaling down by λ (i.e., identical under translation and rotation). The fractal or similarity dimension D of the set S then follows the relation $N\lambda^D = 1$. For self-affinity, however, each of the N subsets is scaled down from the whole by a different λ_n , satisfying $\sum_{n=1}^N \lambda_n^D = 1$.

A self-affine series $h(x)$ defined along a profile of length L can be formulated with Fourier sine series as $h(x) = \sum_{n=1}^{\infty} A_n \sin(2\pi nx/L)$, where the coefficient A_n is related to wave length $\lambda_n = L/n$, $n = 1, 2, 3, \dots$ through a power-law $A_n = C\lambda_n^{\frac{2-D}{2}}$, where C is constant and D the fractal dimension (Turcotte 1991); this relation was obtained by counting the number of rectangular boxes of various sizes to cover the self-affine profile in contrast to the square boxes of a given size used to cover the self-similar profile.

For a 1-D profile of slip roughness, self-affinity means invariance of roughness of a profile observed at direction-dependent different scales and is characterized by a power-law dependence of power spectrum on wave-number k as $p(k) \propto k^{-\beta}$, with $\beta = 2H + 1$. Cross-sections of topography and bathymetry are examples of self-affine function (Brownian motion or random walk) where the height scales as $|h(x+l) - h(x)| \approx l^H$; they can be reproduced by integration of white Gaussian noise ($\beta = 0$).

Scaling of Earthquake Sources

Earthquake scaling, generally referred to as self-similar unless otherwise stated, implies identical physics of earthquake sources under a change of scale. This means that similar physics holds good for all earthquakes regardless of

size, depth, tectonics, and geology. Figure 1A demonstrates the concept of earthquake scaling. Increase in earthquake size by a factor of b scales (increases) the displacement, fault area, and seismic moment by b , b^2 , and b^3 , respectively. Self-similarity predicts, for an identical source-receiver geometry in a loss-less media with constant rupture velocity between earthquakes, that the far-field displacement pulse will increase in duration by b , and in amplitude by b^2 ; the displacement spectra of different earthquakes scaled proportionally have identical shapes but shifted along the ω^{-3} line, as found from the use of similarity theorem in frequency domain (Prieto et al. 2004).

There is a long-standing debate on the existence scaling in seismology: whether stress drop and apparent stress (ratio of seismic energy to seismic moment) are constant, independent of seismic moment (or magnitude). One way to test this hypothesis is stacking of the log spectra of P - and S -waves, after the events are corrected for site and path-related effects. The identical shapes of the log spectra of events of different moment bins that are offset along the ω^{-3} line (Fig. 1B) (Prieto et al. 2004) suggest self-similarity of earthquake spectra. Observations such as the (i) $f_c \propto M_0^{-1/3}$ relation between the corner frequency and seismic moment, and (ii) almost constant apparent stress with moment, suggest a self-similar constant stress-drop scaling for the events (M_L 1.8–3.4) in southern California.

Limited bandwidth of the recorded events underestimates the seismic energy, with the energy more than the corner frequency lacking from the data (missing energy). The events, corrected for such finite bandwidth effects, show almost constant values of apparent stress (3×10^{-5}) and stress drop (1 MPa) over 17 orders of seismic moment (Ide and Beroza 2001) (Fig. 1C). They report that any departure from self-similar scaling could be a manifestation of inadequate correction of data during pre-processing for the site- and path-related effects, finite-frequency effects, etc. (for reviews see Ide and Beroza 2001; Prieto et al. 2004; Padhy and Subhadra 2016 and references therein).

Scaling of Distribution in Slip Roughness

Roughness in fault/fracture surface exhibits fractal geometry, but it is not yet clear whether slip distribution of real earthquakes is self-similar or self-affine. Spatial correlations of slip maps compiled from large earthquakes show self-affinity behavior with an average $H = 0.71 \pm 0.23$, regardless of size and source dimension (Mai and Beroza 2002). Self-affine roughness for the H values different from 1.0 implies a larger roughness variability compared to self-similarity ($H = 1.0$). A generalized self-affine fractal, in the assumption of anisotropic fractal roughness, properly explains both constant stress-drop (static) and complex rupture propagation (dynamic) models of earthquakes. Heterogeneity in slip can

stochastically be described by spatially filtered random functions with a spectral decay of $k^{-\alpha}$, where k is wave number and the exponent α , a measure of smoothness in spatial slip distribution. This slip model helps in (i) interpreting the scaling of average slip with rupture length ($\alpha \sim 1.5$ suggests constant slip-length ratio and thus constant stress drop), and (ii) correlating with frequency-size event statistics ($\alpha < 1.5$ implies more small events than large ones) (Liu-Zeng et al. 2005).

Stress and strain changes corresponding to the slip-distribution of the type mentioned above have a spectral decay of $k^{-\alpha+1}$, $\alpha = 1.0$ represents a Gaussian and $\alpha < 1.0$ representing stress changes that are deficient in long-wavelength variations compared to random functions. In 2-D, the amplitude spectrum of the stress field can be expressed as $\tau(k) \propto k_c^{-(1+H)} = \text{const}$ for $k \leq k_c$, and $\tau(k) \propto k^{-(1+H)}$ for $k > k_c$ (Mai and Beroza 2002), where $k = \sqrt{k_x^2 + k_z^2}$ in x-z plane, suggesting that the spectral decay

is governed by the Hurst exponent H above the corner wave number k_c . The random stress field is stochastically realized by the exponent H and the correlation length $a_c = \frac{2\pi}{k_c}$. The exponent H governs the high wave-number fall-off of the stress heterogeneity spectrum that is related to fractal dimension D by $D = d + 1 - H$, d the Euclidean dimension. The stress spectrum takes the form of $|\tau(k > k_c)| \propto k^{-1}, k^{-1.5}, k^{-2}$

for $H = 0, 0.5$, and 1.0 , where $|\tau(k)| \propto k^{-1}$ corresponds to the self-similar scaling (stress drop independent of rupture size).

Figure 2a shows the map of slip roughness of size (512 points $\times$ 512 points) generated from one random realization with the H values along the X - and Y -axes: ($H_x = 0.6$, $H_y = 0.8$ for self-affinity (**left panel**) and $H_x = H_y = 1.0$ for self-similarity (**right panel**). The slopes of the power spectra

(**Left panel**) (a) Map of fault roughness generated with one of the random realization of the stochastic process ($H_x = 0.6$, $H_y = 0.8$). (b) Roughness along the two selected profiles parallel to X - and Y -axes. (c–d)

power spectra of the profiles shown in (b). The spectral exponents estimated from the slopes to the spectral fits (solid lines) are shown. (**Right panel**) Same as the left panel, but for a self-similar distribution ($H_x = H_y = 1.0$)

of the two profiles selected along X - and Y -axes of the map are compared for both the scaling types (Fig. 2b–d); their spectral dimensions are nearly the same for the self-similar surface, while they differ for self-affinity, as expected. The roughness variability for the self-similar surface is relatively smoother than that for the self-affine one, because of the variation with direction of roughness for the latter.

Unified Scaling Law

There is a widespread evidence of earthquake scale-invariance from observations such as the magnitude (m)/energy (s)

distribution in time $N(M > m) = 10^a - b m$, $N(S > s) \propto s^{-b}$, $m = \log s$, $b \sim 1$ (Gutenberg-Richter, G-R law) (Fig. 3a), the temporal correlation T^{-p} , $p \sim 1$ (Omori law), $m \propto \log(cM_0)$ ($c \sim 1.5$), $M_0 \propto A^{3/2}$, $N(S > s) \propto L^{-D}$ (M_0 : seismic moment, A : rupture area, L : rupture length, and D : fractal dimension) and space-time clustering of events with a fractal distribution (Dimri 2005). Unified scaling law provides a framework explaining all these features together, where a scale of $S^{-b}L^D$ is suggested combining S and L (Bak et al. 2002). The distribution of time interval between two successive earthquakes (waiting time) T occurring within an area of size L with magnitudes more than m shows a band-limited power-law regime with a cut-off (upper limit) waiting time (Fig. 3b). It shows the

Fractal Scaling of Earthquakes, Fig. 3 Unified scaling law and SOC. (a) Magnitude (≥ 2) distribution of earthquakes (circles) in California. The G-R frequency-size distribution (solid line) with $b \sim 0.95$ is shown. (b) Distribution of waiting time between earthquakes shown for different values of cut-off magnitude S (or m) and areal extent of size L : $m = 2$ (circles), 3 (squares), and 4 (triangles); and $L = 0.25^\circ$ (black), 0.5° (red),

2° (blue), and 4° (orange). (c) Presentation of rescaled data shown in (b) for $T > 38$ s, re-plotted with $T^\alpha P_{SL}(T)$ as a function of $x = c T S^{-b} L^D$, $c = 10^{-4}$. The inverted arrow marks the region of correlated power-law regime from uncorrelated one. The values $\alpha = 1$, $b = 1$, $d_f = 1.2$ allow all data to fall onto a single curve. (Bak et al. 2002; © 2002 APS)

Omori law regime increases with increasing S (or m), and decreases with increasing L . Rescaling the axes [$x = TS^{-b}L^D$ and $y = T^p P_{S,L}(T)$] of Fig. 3b shifts the curves, causing them to fall onto a single curve $y = f(x)$, implying a unified scaling law for earthquakes (Fig. 3c) (Bak et al. 2002). Temporal correlation of events is thus decided by the product $x = TS^{-b}L^D$ but not on T , S , and L individually. The curve $f(x)$ is almost constant over eight orders of magnitude for $x < 1$, corresponding to a correlated Omori law regime, while it decays fast for $x > 1$, related to uncorrelated events (Bak et al. 2002). Any departure from power-law scaling can significantly be reflected with this analysis.

Statistical Treatment of Fractal Heterogeneities in Earth

Heterogeneities in the earth are fractal in a wide scale range. The growth of fractal structures is attributed to several geological processes. It is of considerable interest to study those processes quantitatively through fractal analyses of the distributed heterogeneities in geological structures. The fluctuations in seismic velocity can be realized with a random function $f(\mathbf{x})$ of zero mean $\langle f \rangle = 0$ and finite covariance defined by $\langle f(\mathbf{x})f(\mathbf{x} + \mathbf{r}) \rangle = \sigma^2 N(\mathbf{r})$, where σ is the standard deviation and $N(\mathbf{r})$ the ACF with $N(\mathbf{0}) = 1$. The energy spectrum can be obtained from the Fourier spectrum of the ACF as $E(\mathbf{k}) = \sigma^2 \int N(\mathbf{r}) e^{-i\mathbf{k} \cdot \mathbf{r}} d\mathbf{r}$, where $\mathbf{k}$ is the wave vector. The self-affine fractal properties of the medium inhomogeneities can be described by the vonKarman ACF as $N(\mathbf{r}) = \frac{2^{1-H}}{\Gamma(H)} \left(\frac{r}{a}\right)^H K_H\left(\frac{r}{a}\right)$, and the corresponding energy

$$\text{spectrum as } E^d(\mathbf{k}) = \sigma^2 \left| \frac{\Gamma(H+\frac{d}{2})}{\Gamma(H)} \right| \pi^{d/2} \frac{(2a)^d}{(1+a^2 k^2)^{H+\frac{d}{2}}} \quad (\text{Lord 1954}),$$

where a is correlation length, H the Hurst exponent characterizing the roughness of the medium, and d is Euclidean dimension. The energy spectrum of the distributed heterogeneities is used to predict wave propagation and scattering of seismic waves in 3-D fractal media.

Seismic Attenuation in Fractal Media

Seismic waves at high frequencies (say, 1–25 Hz) undergo scattering from heterogeneities in velocity with length scale in the range of a few hundred meter to a few kilometer. Other heterogeneities on the similar scale length could be in the density, geometry or fluid content of cracks/fractures associated with shear faulting. A fractal medium refers to scale-invariance in fractures/faults in the earth's crust, suggesting that (a) all the cracks have same aspect ratio, (b) crack-lengths are power-law distributed, and (c) fracture surfaces have the same roughness (Main et al. 1990). There is an upper and lower bound to the length scale defining the power-law (band-limited self-affine law). This band-limited fractal geometry satisfies the physical processes at a finite range of frequencies in order to satisfy the Kramers-Kronig relation for explaining the frequency dependence of attenuation in the lithosphere, characterized by a dimensionless factor $Q(f)$ (Main et al. 1990). In 3-D, the power spectrum of the heterogeneities in velocity produced by distributed cracks takes the form $S(k) \propto k^{-\beta}$ that explains the power-law frequency dependence of Q^{-1} as $Q^{-1} \propto \omega^3 - \nu$.

For a fractally homogeneous spatial distribution of scatterers with number density $n(r)$ [$n(r) \propto r^{D-3}$], where r is

Fractal Scaling of Earthquakes,

Fig. 4 Dependence of seismic energy with distance for different values of fractal dimension in a fractal medium of fractally distributed heterogeneities

distance and D is fractal dimension, energy decay with distance of seismic waves can be expressed as $J(r) = \frac{1}{4\pi r^2} e^{\left[-\frac{G}{D-2}r^{D-2} + \text{const}\right]}$ for $D \neq 2$ and $J(r) = \frac{1}{4\pi r^2} \frac{\text{const}}{r^G}$ for $D = 2$, where G is a constant, a measure of scatterer cross-section (Sato 1988). Exponential decay of energy with distance is described as a special case for $D = 3$ (Sato 1988). Figure 4 shows the energy decay with distance for different values of fractal dimension obtained from the above expression with $G = 1$, and $\text{const} = 1$, illustrating the dependence of the shape of the decay with fractal dimension.

Summary and Outlook

Scaling, a powerful technique in science, allows one to analyze earthquake process on any other scale than it is observed. Earthquake phenomena described by fractal distributions are said to scale, meaning that same physics must work at different scales analyzed. Scaling analyses can detect regions of power laws and its types in earthquake data. Observation of self-similar power-law scaling in seismology is widespread. Presence of more than one distinct scaling region in 1-D signal suggests to go beyond self-similarity (multi-fractality and hence self-affinity as its special case), however. In 2-D, self-affine, rather than self-similar map of slip roughness can tell us larger and anisotropic roughness variability. Such detailed source slip models are important for high-frequency ground-motion modelling. There is a great debate on the existence of self-similar scaling in earthquake studies, which needs proper treatment of high-quality data (sufficient data length, wide magnitude range, etc.) before interpretation. Inadequate corrections of the data for the path- and site-related and finite-frequency effects (lack of energy at frequency more than the corner-frequency) may yield biased estimates of scaling relations. Also, the use of correct theory in deriving the scaling laws is important. The unified scaling functions that can rescale the multidimensional (space, time, and magnitude) scaling relationships to a function of single variable confidently detects the region of power-law regime in the distribution. The analogy among the scale invariance of earthquake processes, observation of self-similar earthquake statistics and self-similar structures at different scales is still poorly understood, which probably needs detailed numerical studies to explain observed scaling relations.

Definition

Fractals – Often refers to the geometry of the objects. Objects having a fractional dimension are termed as a fractal. Also, such objects are self-similar in nature; thus, their shape is independent of the scale and remains the same under dilatation or contraction. The concept is extended to the time series analysis, and the time series in which the power spectrum follows power law is termed as “fractal time series.”

Chaos – Often refers to the dynamic state of a system. The behavior of chaotic systems is highly sensitive to initial conditions. A small change in initial conditions, even due to rounding-off errors in computation, can yield widely diverging outcomes for chaotic systems, rendering long-term prediction impossible. The chaos can be quantified by Lyapunov exponent if it is positive.

Introduction

The origin of fractals dates back to the eighteenth century in the study of nondifferentiable functions by Karl Weierstrass, Georg Cantor, and Felix Hausdorff; however, the term fractal was coined by Mandelbrot (1967, 1983) in a paper published in science “How long is the coast of Britain?” and later in his book “Geometry of Nature.” Fractals and Chaos are relatively new mathematical innovations, which find their applications in several branches of pure and applied sciences. Applications of fractals and chaos have been widely explored in solid earth geophysics, and its successful applications are demonstrated in many areas of geophysics viz: gravity, magnetic modeling (Turcotte 1997; Dimri 2005; Maus and Dimri 1995), seismic inversion, earthquake frequency magnitude relationship (Ouchi and Uekawa 1986; Dimri et al. 2005), analysis of reflectivity sequence (Painter et al. 1995; Toverud et al. 2001), and fractal representation of soil structures to characterize soil water properties in terms of porosity and particle size distribution (Rieu and Sposito 1991). Another important study is the simulation of fractures using a fractal method (Borodich 2000; Tanaka et al. 2001; Dimri and Srivastava 2019). Chaos has been used in studies related to the atmosphere, climate, and earthquake studies (Grassberger and Procaccia 1983; Srivastava 2005).

Basic Concepts

Power Law (Scaling Behavior)

Spectral analysis of fractal time series shows that power (P) is proportional to frequency (f) raised to power a real exponent (β), termed as scaling exponent (Fig. 1a, e). In mathematical form it is represented as:

$$P(f) \propto f^{-\beta} \quad (1)$$

This behavior is also known as scaling law.

The fractal analysis of time series is fundamentally based on the concept of fractional Brownian motion and fractional Gaussian noise. The fractal time series, also known as time series having long memory are characterized by fractional Gaussian noise (fGn). A time series is said to follow fGn characteristic (i) if its histogram is fat-tailed Gaussian,

(ii) Covariance, semivariogram, and power spectrum follows power-law behavior, and (iii) Hurst coefficient lies within [0.5, 1.0] as shown in Fig. 1. A popular method of Hurst coefficient estimation is Re-Scaled range analysis (R/S analysis). Below we discuss the definition and basic concepts of fractional Brownian motion and fractional Gaussian noise.

Fractional Brownian Motion (fBm)

Fractional Brownian motion is a generalization of classical Brownian motion (cBm). The fractal nature of fBm can be understood from the following mathematical definition. Assume that $f(t)$ is a single-valued continuous function of time/space (t). Let the increments (or difference of adjacent values) $\delta f = f(t_2) - f(t_1)$ follow Gaussian distribution (Molz and Boman 1993) with the following properties:

$$\left. \begin{aligned} E < f(t_2) - f(t_1) > &= 0, \text{ and} \\ E < [f(t_2) - f(t_1)]^2 > &= \alpha |t_2 - t_1|^{2H}, \end{aligned} \right\} \quad (2)$$

where $E<X>$ is the mean or expected value of X , α is constant of proportionality and H is an exponent known as Hurst coefficient (Mandelbrot and Van Ness 1968; Voss 1985a, b) lying between 0 and 1 ($0 \leq H \leq 1$). The expected values are obtained by averaging over many increments of size $|t_2 - t_1|$. The equation (2) holds for any value of time increment $\delta t = |t_2 - t_1|$. It is obvious from equation (2) that for $H = 0.5$, $E < [f(t_2) - f(t_1)]^2 > = \alpha |t_2 - t_1|$, so the fractional Brownian motion reduces to classical Brownian motion (cBm).

Fractional Gaussian Noise (fGn)

The concept of fractional Gaussian noise is intertwined with the fractional Brownian motion. The detailed discussion and criteria to distinguish between these two are explained in the paper by Hewett (1986) and Hardy and Beier (1994). Here we describe in brief the relationship between fBm and fGn.

Let, $x_1, x_2, x_3, \dots, x_n$ be the sequence of numbers separated by time interval δt that represents a fBm process, then one can generate corresponding fGn or time derivative process by computing the sequence $[(x_2 - x_1), (x_3 - x_2), (x_4 - x_3), \dots, (x_n - x_{n-1})]/\delta t$. Conversely, if one starts with a fGn sequence of numbers given by $y_1, y_2, y_3, \dots, y_n$, then numerical integration will yield the corresponding fBm sequence given by:

$[y_1, (y_1 + y_2), (y_1 + y_2 + y_3), \dots, (y_1 + y_2 + y_3 + \dots + y_n)]$. A time/space series with Hurst coefficient $H > 0.5$ is characterized as fGn.

Fractal Signal Analysis

Geophysical signals are often in the form of time/space series, which can be characterized by a combination of stochastic

Fractals and Chaos, Fig. 1 Test of fractal behavior of the time series (a) given neutron porosity (NPHI) well log data (b) Histogram of the NPHI well log data (c) Covariance of the NPHI well log data (d) Semivariogram of the NPHI well log data (e) Log power spectrum of

the NPHI well log data (f) Hurst coefficient ($H = 0.80$) of the NPHI well log data showing fractional Gaussian noise (fGn) characteristic of the well log

component, trend component, and periodic component (Malamud and Turcotte 1999). To quantify the stochastic component of the time series, it is necessary to specify the statistical distribution of values and persistence. There are a variety of techniques to quantify the strength of persistence, but the most commonly used is the spectral analysis, where the Fourier spectrum of time series is plotted against frequency (or wavenumber in case of space series) and the value of the slope, known as scaling exponent (say β), gives an estimation of persistence. Persistence study is useful in understanding the nature of the phenomenon. Depending upon the value of scaling exponent, persistence can be characterized as “weak” or “strong.” Scaling exponent controls the balance of high and low frequencies and determines the degree of smoothness or correlation of the time series.

Analyzing Geophysical Time Series

Persistence of the time series is a measure of the correlation between adjacent values of the terms in time series. The

uncorrelated or random data with zero persistence is the white noise. The case $\beta = 0$ (Fig. 2a) has a power spectrum, independent of frequency, and is white noise. The values of such a time series are uncorrelated and completely independent of one another. The time series is antipersistent if adjacent values are anticorrelated. When $\beta < 0$ (Fig. 2b), the series is anticorrelated and each successive value tends to have the opposite sign. Noise with $\beta = -1$ is sometimes called flicker noise, while that with $\beta = -2$ is the Brownian noise. The time series is persistent if adjacent values are positively correlated to each other. For $\beta > 0$ (Fig. 2c), the series is positively correlated, i.e., persistent. Most of the well-logs exhibit antipersistent character, whereas reflectivity shows persistent character.

Fractal Behavior of Various Physical Properties

The Earth’s inherent complexity makes it challenging to infer the location, distribution, and structure of rock types, grain size distribution, material strength, porosity, permeability,

Fractals and Chaos, Fig. 2 Power spectrum of (a) random data, (b) antipersistent data, and (c) persistent data. (Modified from Dimri 2005)

etc. from the direct observations; these characteristics are often inferred from the distribution of fundamental physical properties such as density, electrical conductivity, acoustic impedance, and many others properties. For a geophysical study, the physical response of the Earth can be approximated by the convolution model (Dimri 1992). The extraction of useful information from the observations made over the surface needs advanced processing and interpretation techniques. Physical properties of the earth system follow fractal (scaling) distribution. Examples showing the scaling power spectrum of well-log data from deep KTB pilot borehole are shown in Fig. 3. Observed scaling distribution of physical properties is contrary to the commonly assumed random distribution of properties, which offers simple mathematical formulation. An attempt has been made to reformulate interpretation techniques of geophysical exploration based on scaling (fractal) distribution of physical properties (Dimri 2005; Dimri et al. 2012).

Fractals in Seismology

Fractal concepts can be efficiently used to characterize the seismicity pattern of a region. The fractal nature of the spatial

distribution of earthquakes was first demonstrated by Kagan and Knopoff (1980), Hirata and Imoto (1991), and Hirabayashi et al. (1992). The hypocenter distribution data suggest that the changes in fractal dimension could be a useful precursor parameter for earthquakes as it is a measure of the degree of clustering of seismic events. A change in fractal dimension corresponds to the dynamic evolution of the states of the system. Generally, the values of fractal dimension cluster around 1 when the system is relatively stable and decreases to lower values around 0.3 prior to the failure. The decrease in the value of the fractal dimension before a big earthquake is observed by several authors (Ouchi and Uekawa 1986; De Rubies et al. 1993). Hirata et al. (1987) showed that the change in fractal dimension with time is mainly dependent on the crustal conditions of the study region. On similar lines, fractal characteristics of the spatio-temporal sequence were studied to understand the seismic activity in one of the most active seismic zones, the “Circum-Pacific Seismic Belt” and its vicinity (Yin et al. 2019).

A recent study (Chen et al. 2020) reveals that the occurrence of strong (Magnitude >6.0) shallow earthquakes appears to follow a fractal pattern called Devil’s Staircase

Fractals and Chaos, Fig. 3 Power spectrum of (a) Density (b) Susceptibility (c) Electrical resistivity, and (d) Thermal conductivity. (Data from KTB borehole, Germany)

(also known as Cantor function), where clusters of earthquake events are separated by long but irregular intervals of no earthquakes. This finding differs from the previous pattern prediction by classical earthquake modeling that suggests the periodic or quasiperiodic occurrence of earthquakes based on cycles of build-up and release of tectonic stress. In nature, Devil's Staircase pattern is found in sedimentation sequences. Changes in uplift and erosion rates and reversals in Earth's magnetic field, among many other examples.

Fractal Porous Media

Discussion on the fractal theory for the solid Earth geophysics would be incomplete without a comprehensive discussion on the porous media. Studies have shown that porous media exhibit fractal characteristics, and since then, several attempts have been made to describe the fractal characters of a porous media. The properties like porosity and permeability have steadily attracted much attention in the past decades to describe the flow in fractal media (Vadapalli et al. 2014; Chattopadhyay and Vedanti 2016). The fractal characteristics are being used to model the fluid flow in complex fractured media. An analytical model of dimensionless permeability developed on the basis of the fractal theory is proposed by

Miao et al. (2019) for a porous media. In the latest development, it was demonstrated that the surface conductivity also obeys a power-law dependence on the specific surface area, called as surface Archie's law, and the power exponent is theoretically related to the porosity exponent entering Archie's law and to the fractal dimension of the pore network. Thus, a new permeability model is derived by combining the new surface Archie's law and the Kozeny–Carman model (Wang and Revil 2020).

Chaos

And now a bubble bursts, and now a world
- An essay on Man, Alexander Pope

Chaos theory is a branch of mathematics that deals with nonlinear dynamical systems. Nonlinear means that due to feedback or multiplicative effects between the components, the result becomes something more significant than just adding up the individual parts. Dynamical means the system changes over time based on its current state (Boeing 2016). The concept of chaos was proposed by Lorenz, who advocated that a small perturbation in the coupled system can

amplify to a great deal in some other part of the system. The chaotic systems are known to have a finite fractal dimension (Moharir 2000). The chaotic behavior of the system can be assessed by the quantitative estimate of Lyapunov exponent. The Lyapunov exponent measures the sensitivity of a dynamical system to small changes in the initial conditions and used for identifying chaos. For instance, if two orbits start close to each other in a chaotic system, then they will tend to move apart from each other exponentially. This process can be mathematically expressed as (Taylor 2005):

$$\frac{d}{d_0} = e^{\gamma(t-t_0)} \quad (3)$$

where d_0 is the initial displacement between a starting point and a nearby neighbor at initial time t_0 . The variable d is the displacement at time $t > t_0$. The γ is the Lyapunov exponent. It is evident from equation (3) that if $\gamma > 0$, then d/d_0 grows exponentially with time; if $\gamma < 0$, then d/d_0 tends to zero, and if $\gamma = 0$, then the change in displacement with time is non-exponential. The above equation (3) can be used to calculate

Lyapunov exponent, and a system is said to be chaotic if the Lyapunov exponent is positive (> 0).

Various evolutionary fluctuations exhibit the features of a dissipative dynamical system with possible chaos in phase space (Tiwari 2000). If all the trajectories of evolutionary processes converge toward a subset of phase space irrespective of their initial conditions, then the subset is called an “attractor” (Tsonis and Elsner 1988). There are mainly two types of attractors, nonstrange and strange attractors. There are three known types of nonstrange attractors, (a) fixed point attractor, (b) limit cycle attractor, and (c) torus attractor. These are nonfractal attractors with predictable behavior. Each of the three nonstrange attractors is associated with a specific type of orbit behavior (trajectory). The *fixed point* is associated with attractors whose orbits approach an equilibrium state; the *limit cycle* corresponds to periodic motion, and the *torus* corresponds to quasiperiodic motion orbit (Fig. 4).

Attractor provides a vital link between Chaos theory and Fractal geometry. The nature of the attractor is characterized by its fractal dimension. A “strange attractor” will have a noninteger (fractal) dimension. The term strange is used to

Fractals and Chaos, Fig. 4 Trajectory of the types of attractors: (a) point attractor obtained from a solution of a 2D differential equation (b) periodic limit cycle attractor obtained from Vande pol oscillator

(c) quasiperiodic attractor is a solution of Lorentz ODE using Rossler approach (d) Chaotic attractor is a solution of Lorentz ODE

those attractors showing extreme sensitivity to the initial condition, often they are chaotic, but it is not essential (they can be nonchaotic). In a chaotic regime, orbits on an attractor are nonperiodic; thus, the orbit behavior (or trajectory) of the chaotic attractors is a strange geometrical structure that is fractal in nature. The orbit behavior of a strange attractor is shown in Fig. 4d, which is nonperiodic and nonpredictable. The fractal dimension of a chaotic system indicates the number of ordinary differential equations needed to model the process, or in other words, it is indicative of the number of variables required for an almost complete description of the dynamic system (Tsonis and Elsner 1988).

Summary

Geophysical interpretation techniques have been reformulated after the findings from the analysis of physical properties recorded in different deep bore wells worldwide, which shows that the physical properties of the earth system follow fractal instead of random distribution (Dimri 2005). Research in solid earth geophysics employing fractals and chaos includes modeling of earth's magnetic and gravity fields, and it has been shown that the rocks have "scaling" stratification (Lovejoy et al. 2008; Lovejoy and Schertzer 2007). Another significant research in this field includes simulation of fGn series, which helps to improve the inversion results by way of providing a suitable initial model (Srivastava and Sen 2009, 2010). In atmospheric sciences, interesting research is done to model the atmospheric dynamics, which repeats scales after scales and behaves like a cascade (Lovejoy et al. 2009). There are several interesting applications of chaos in climate and rainfall modeling (Hosking 1984; Sivakumar 2000).

Free Oscillations of the Earth

Sarva Jit Singh¹ and Sunita Rani²

¹Indian National Science Academy, New Delhi, India

²Department of Mathematics, Guru Jambheshwar University of Science and Technology, Hisar, India

Definition

Free oscillations of the Earth are standing waves along the surface of the Earth. These oscillations are typically observed after a large earthquake or an explosion because the Earth starts to vibrate as a whole as does a ringing bell when it is struck. The study of the Earth's free oscillations is based on the theory of vibrations of an elastic sphere. The problem increases in complexity as we proceed from an isotropic homogeneous sphere to models of the Earth which take into

account its anelasticity, anisotropy, radial and lateral heterogeneity, rotation, gravity, and prestress.

Introduction

The seismological data can be analyzed and interpreted in terms of three basic concepts. The first is based on the geometrical ray theory of optics. Most of our knowledge about the interior of the Earth has come from the application of the ray-theoretic methods to seismological data. Ray theory is useful for periods shorter than a minute. Travel times of seismic phases constitute an important component of the ray theory concept.

The second concept is that of surface waves. The study of the dispersion of surface waves helps us in determining the regional structure, e.g., low-velocity zones, oil-bearing structures, etc. The surface wave theory is useful in the period range 10–300 s.

The third concept is that of the normal-mode theory or free oscillations of the Earth. In here, the field is viewed as a sum of standing waves instead of travelling waves. The standing waves can be seen as peaks in the amplitude spectrum of a seismogram. Theoretical seismograms can be computed for spherically symmetric, nonrotating, elastic, isotropic (SNREI) Earth models by mode summation techniques at low frequencies. At high frequencies, the number of modes required to represent the field becomes so large that the mode summation technique is not practicable.

The problem of the oscillations of an elastic sphere is an old one. It attracted many classical physicists of the nineteenth century, including S.D. Poisson, Lord Kelvin, G.H. Darwin, and H. Lamb. In a classic paper, Lamb (1882) discussed the various modes of oscillations of a uniform elastic sphere and calculated the important roots of the frequency equation. He classified the oscillations of a sphere as of the “first class” and the “second class.” In an oscillation of the first class, the dilatation and the radial component of the displacement vanish everywhere so that there is no change of shape. In the case of the oscillations of the second class, the radial component of the vorticity vanishes. The oscillations of the first class are now known as toroidal or torsional oscillations and the oscillations of the second class as spheroidal or poloidal oscillations.

The Earth differs from a homogeneous elastic sphere in two important respects: self-gravitation and radial heterogeneity. Gravity does not affect the toroidal oscillations because these are divergence-free and have no radial component of the displacement, so that the density distribution remains unchanged. But gravity plays an important role in the case of the spheroidal oscillations. Bromwich (1898) investigated the effect of self-gravitation, simplifying his work by dealing only with an incompressible sphere. Love (1911)

showed that a self-gravitating sphere of the size and mass of the Earth and of rigidity that of steel has a free period of oscillation of almost exactly 1 h for the mode ${}_0S_2$ (the fundamental mode of the spheroidal oscillation of the second order). Obviously, if this mode were to be observed, instruments would be needed that had sensitivity at periods very much longer than the periods of seismic motion then being routinely recorded.

Shida (1925) designed an electromagnetic seismograph with pendulum period 180s and galvanometer period 1200s for observing Earth's free oscillations. However, the technology of that time was incapable of achieving the precision and sensitivity that were demanded. It was Hugo Benioff who first constructed an electromagnetic strainmeter which was capable of recording free vibrations for as long as 1 h. However, he had to wait for a big earthquake to make an appropriate use of the strainmeter developed by him, since the Earth will produce its deeper modes only when a large amount of kinetic energy is released by an earthquake or an explosion.

Benioff was able to record a ground motion of 57-min period for the Kamchatka earthquake of 4 November 1952 on his strainmeter. He (Benioff 1958) attributed it to the mode ${}_0S_2$ of the oscillations of the Earth. This was the first time that the natural oscillations of the whole Earth had been observed. It was but natural that several seismologists started investigating the problem of the free oscillations of the Earth theoretically and calculating the periods of the normal modes of real Earth models. Jobert (1956) applied Rayleigh's principle in calculating the period for the mode ${}_0T_2$ (the fundamental mode of the toroidal oscillation of the second order) as 43.54 min for the Bullen B model of the Earth. In the following year, Jobert (1957) applied the same method in obtaining the period for the mode ${}_0S_2$ as about 53 min. Pekeris and Jarosch (1958) applied variational methods in calculating the period of the mode ${}_0S_2$ as 53 min. Soon after, Alterman et al. (1959) integrated the equations of motion numerically and calculated the periods of various normal modes of the Earth. In particular, they showed that the period of the mode ${}_0S_2$ should be 53.7 min for Bullen B model of the Earth. A wide range of normal modes of the whole Earth was observed by several seismological groups in the USA for the great Chilean earthquake of 22 May 1960. The agreement between the observed periods and the periods calculated by Alterman et al. (1959) was excellent. This was the beginning of a new branch of seismology – the low-frequency seismology. Impetus to research in this new field was provided by several factors: (i) availability of instruments capable of recording long-period oscillations of the Earth; (ii) availability of high-speed electronic computers for Fourier analysis of the recorded data; and (iii) availability of computer codes for numerical solution of differential equations efficiently.

A network of low-noise accelerometers deployed all over the globe in the 1970s permitted routine detection of normal-mode spectral peaks following earthquakes of relatively modest magnitude.

Observations of the 1960 Chilean earthquake indicated that the mode ${}_0S_2$ did not have a single spectral peak but, instead, was composed of at least two lines with periods 53.1 and 54.7 min. Indeed, Backus and Gilbert (1961) and Pekeris et al. (1961) showed theoretically that for the mode ${}_0S_2$, five spectral lines exist if the rotation of the Earth is taken.

The work of Alterman et al. (1959) and their contemporaries did not include the effects of lateral heterogeneity, ellipticity, prestress, anisotropy, and anelasticity. Considerable progress has since been made in the direction of taking one or more of these features into account. Madariaga (1972) studied toroidal oscillations of a laterally heterogeneous Earth. Kanamori and Anderson (1977) and Woodhouse (1980) discussed the effect of the departure from perfect elasticity. Woodhouse and Dahlen (1978) investigated the effect of a general aspherical perturbation on the free oscillations of the Earth. Excellent reviews on the free oscillations of the Earth have been given by Stoneley (1961), Alterman et al. (1974), Lapwood and Usami (1981), Buland (1981), Dahlen and Tromp (1998), and others.

Toroidal Oscillations of a Uniform Elastic Sphere

On applying the method of separation of variables, the equation of motion for the toroidal oscillations of a homogeneous isotropic (uniform) elastic sphere of density ρ and Lamé's parameters λ and μ leads us to the following equation for the radial eigenfunction $W(r)$

$$\frac{d^2W}{dr^2} + \frac{2}{r} \frac{dW}{dr} + \left[\frac{\rho\omega^2}{\mu} - \frac{l(l+1)}{r^2} \right] W = 0, \quad (1)$$

where ω is the angular frequency and $l = 0, 1, 2, 3, \dots$ is a separation variable. Equation (1) can be solved in terms of the spherical Bessel functions. Solution of Eq. (1), which remains bounded as $r \rightarrow 0$, is of the form

$$W = A_0 j_l(\omega r/\beta), \quad (2)$$

where $j_l(\chi)$ is the spherical Bessel function of the first kind and $\beta = (\mu/\rho)^{1/2}$ is the shear wave velocity. The boundary condition that the surface $r = a$ of the sphere is traction-free yields the frequency equation:

$$\chi j_{l+1}(\chi) = (l-1)j_l(\chi), \quad (3)$$

where $\chi = \omega a/\beta$.

Since the frequency equation (3) is a transcendental equation, for each l , it possesses an infinite number of roots in χ . Let these roots be numbered in ascending order of magnitude and denoted by ${}_n\chi_l$ ($n = 0, 1, 2, \dots$). The corresponding frequencies and periods can be found through the relations.

$${}_n\omega_l = (\beta/a){}_n\chi_l, {}_nT_l = 2\pi/{}_n\omega_l. \quad (4)$$

Then ${}_n\omega_l$ are the eigenfrequencies, and ${}_nT_l$ are the eigenperiods. Further, $n = 0$ is associated with the fundamental mode, and $n = 1, 2$, etc. are associated with the first overtone, the second overtone, etc. For a given $l > 0$, there exists a family of n concentric nodal surfaces, i.e., interior surfaces at which the toroidal eigenfunction W vanishes. These nodal surfaces are given by

$$j_l\left(\frac{r}{a}{}_n\chi_l\right) = 0. \quad (5)$$

There are no toroidal oscillations associated with $l = 0$, since the corresponding displacement is identically zero. The value $l = 1$ yields a rigid rotation. The accompanying toroidal oscillations are known as rotatory vibrations. For $l = 1$, the frequency equation (3) becomes $j_2(\chi) = 0$, which may be expressed in the form

$$\frac{\tan \chi}{\chi} = \frac{3}{3 - \chi^2}. \quad (6)$$

The lowest roots of Eq. (6) are given, approximately, by

$$\chi = 5.763, 9.095, 12.322, 15.514 \dots \quad (7)$$

Equation (7) lists the first four overtones. For $l = 1$, the fundamental mode does not exist. For this mode ($l = 1, n = 0$), every part of the sphere shows rotation around some axis in one direction. Such a motion could not be excited without the application of an external torque and so would not be a free oscillation. Consequently, the frequency equation has no root corresponding to this mode (Lapwood and Usami 1981, p. 35).

For rotatory vibrations, the nodal spheres are given by

$$j_1\left(\frac{r}{a}{}_n\chi_l = 0\right)$$

which yields

$$\tan\left(\frac{r}{a}{}_n\chi_l\right) = \frac{r}{a}{}_n\chi_l. \quad (8)$$

Table 1 lists the dimensionless frequencies, periods, and nodal spheres for rotatory vibrations of a homogeneous sphere for the first four overtones.

From Eq. (3), the frequency equation for the toroidal oscillations of the second order ($l = 2$) is given by

$$\chi j_3(\chi) = j_2(\chi),$$

or, equivalently, by

$$\frac{\tan \chi}{\chi} = \frac{\chi^2 - 12}{5\chi^2 - 12}. \quad (9)$$

The corresponding dimensionless frequencies, periods, and nodal surfaces for the fundamental mode and the first four overtones are listed in Table 2.

Spheroidal Oscillations of a Uniform Elastic Sphere

Spheroidal modes corresponding to $l = 0$ are known as radial modes because the associated particle motion is purely radial. The frequency equation for the radial vibrations is (Ben-Menahem and Singh 1981, p. 346)

$$\zeta \cot \zeta = 1 - \frac{1}{4} \left(\frac{\lambda + 2\mu}{\mu} \right) \zeta^2, \quad (10)$$

where

$$\zeta = \omega a / \alpha, \quad \alpha = [(\lambda + 2\mu)/\rho]^{1/2}. \quad (11)$$

It may be noted that the frequency equation for the spheroidal oscillations is a function of the ratio λ/μ . For the Poissonian case ($\lambda = \mu$), the lowest roots of Eq. (10) are given, approximately, by

$$\zeta/\pi = 0.816, 1.929, 2.936, 3.966, \dots \quad (12)$$

Assuming $a = 6371$ km, $\alpha = 9$ km/s, the corresponding periods (in seconds) are found to be

$$T = 1735, 734, 482, 357, \dots \quad (13)$$

The fundamental radial mode ${}_0S_0$ corresponds to an expansion and contraction of the whole sphere without its form changing. For the n th overtone ${}_nS_0$, there are n concentric nodal surfaces inside the sphere at which the displacement vanishes identically.

For $l = 1$, the fundamental mode ${}_0S_1$ does not exist, since it represents a rigid-body translation. Even though the geometric center of the sphere is displaced, its center of mass does not move (Lapwood and Usami 1981, p. 37). Thus the movement of the center does not contradict the physical requirement that the center of mass stays unmoved. The roots of the frequency equation representing the first four overtones ($l = 1, n = 1, 2, 3, 4$) are given, approximately, by

$$\chi = 3.424, 6.771, 7.444, 10.695, \quad (14)$$

assuming $\lambda = \mu$.

In the case of the spheroidal oscillations of the second order ($l = 2$), the oscillating sphere assumes alternatively the forms of a prolate and an oblate spheroid. Therefore, this mode of oscillation is known as the football mode.

Oscillations of an SNREI Earth Model

In the last two sections, we have discussed oscillations of a homogeneous, isotropic, elastic, non-gravitating, spherical

Earth model. This relieves the free oscillation problem of its mathematical intricacies while retaining its important features.

The equations of motion of a spherically symmetric, non-rotating, elastic, isotropic (SNREI) Earth model may be written in the form (Aki and Richards 1980; Ben-Menahem and Singh 1981)

$$\begin{aligned} \operatorname{div} \vec{T} + \rho [\operatorname{grad}(\Psi - gu_r) + \mathbf{e}_r g \operatorname{div} \mathbf{u}] \\ = \rho \partial^2 \mathbf{u} / \partial t^2, \end{aligned} \quad (15)$$

$$\nabla^2 \Psi = 4\pi G \operatorname{div}(\rho \mathbf{u}), \quad (16)$$

where

$\mathbf{u}$ = displacement vector,

$\vec{T} = \lambda \vec{I} \operatorname{div} \mathbf{u} + \mu(\nabla \mathbf{u} + \mathbf{u} \nabla)$ = stress tensor,

g = acceleration due to gravity,

G = gravitational constant,

Ψ = perturbation in the gravitational potential.

Equations (15) and (16) are to be solved subject to suitable boundary conditions. Thus, $\mathbf{u}$, $\mathbf{e}_r \cdot \vec{T}$, Ψ and $\partial \Psi / \partial r - 4\pi G \rho u_r$ must be continuous everywhere. However, at a boundary between a solid and a fluid or between two fluids, u_r rather than $\mathbf{u}$ must be continuous.

In the absence of external body force, the motion of the Earth consists of a superposition of free simple harmonic oscillations of the form

$$\mathbf{u}(\mathbf{r}, t) = \mathbf{u}(\mathbf{r}) \exp(i\omega t).$$

Therefore, the equation which governs the free oscillations of the Earth is obtained from Eq. (15) by making the substitution $\partial/\partial t \rightarrow i\omega$. This yields

$$\mathcal{L}\mathbf{u} + \rho\omega^2\mathbf{u} = 0, \quad (17)$$

where $\mathcal{L}$ is a self-adjoint linear operator. Equations (16) and (17) together with boundary conditions define an eigenvalue problem. Every model of the Earth will possess an infinite number of eigenfrequencies ω_i and a corresponding infinite number of eigenfunctions $\mathbf{u}_i(\mathbf{r})$.

As mentioned in the Introduction, the oscillations of the Earth are of two types – toroidal and spheroidal. At high frequencies, the toroidal oscillations correspond to the Love surface waves and SH body waves. Toroidal eigenfunctions are of the form

$$\mathbf{u}(\mathbf{r}) = W(r)[- \mathbf{e}_r \times \operatorname{grad} Y_{ml}], \quad (18)$$

where

$$Y_{ml} = P_l^m(\cos \theta) \exp(im\varphi)$$

is a surface spherical harmonic. For every value of l except zero, there is a fundamental toroidal mode ${}_0T_l$ and an infinite number of overtones ${}_nT_l$ ($n = 1, 2, \dots$). From Eq. (18) it is seen that for toroidal oscillations, $u_r = \text{div } \mathbf{u} = 0$.

At high frequencies, the spheroidal oscillations correspond to the Rayleigh surface waves and P - SV body waves. The spheroidal eigenfunctions are of the form

$$\mathbf{u}(r) = \mathbf{e}_r U(r) Y_{ml} + V(r) \text{grad } Y_{ml}. \quad (19)$$

For every value of l , there is a fundamental spheroidal mode ${}_0S_l$ and an infinite number of overtones ${}_nS_l$ ($n = 1, 2, \dots$). From Eq. (19), it can be verified that $(\text{curl } \mathbf{u})_r = 0$. On putting $\Psi(r) = P(r) Y_{ml}$, and using Eqs. (18) and (19), Eqs. (16) and (17) can be transformed into a set of four ordinary differential equations of the second order in U , V , W , and P . One of these is an equation in W alone and corresponds to the toroidal oscillations. The remaining three equations are coupled in U , V , and P and correspond to the spheroidal oscillations. These equations are awkward for numerical integration, because one needs to evaluate the derivatives of empirically determined quantities $\lambda(r)$, $\mu(r)$, and $\rho(r)$ in order to obtain the coefficients. This can be formally obviated by converting these equations into an equivalent set of eight linear differential equations of the first order which are free from the derivatives of λ , μ , and ρ . Out of these eight equations, two correspond to the toroidal oscillations and the remaining six to the spheroidal oscillations. We can thus express the equations governing the free oscillations of an SNREI Earth model in the form (Singh 1992)

$$\frac{dY}{dr} = A(r)Y, \quad (20)$$

where Y is an $(N \times 1)$ column matrix and $A(r)$ is an $(N \times N)$ square matrix. The number N depends upon the kind of oscillations and the nature of the medium (Table 3).

From Eqs. (17) and (18), we have the following radial equation for the toroidal oscillations

$$\mu \left(\frac{d^2 W}{dr^2} + \frac{2}{r} \frac{dW}{dr} \right) + \frac{d\mu}{dr} \left(\frac{dW}{dr} - \frac{W}{r} \right) + \left\{ \rho \omega^2 - \frac{l(l+1)}{r^2} \mu \right\} W(r) = 0. \quad (21)$$

This equation involves $d\mu/dr$. Numerical evaluation of the derivative of the empirically determined $\mu(r)$ can be avoided by defining $y_1 = W$, $y_2 = \mu \left(\frac{d}{dr} - \frac{1}{r} \right) y_1$.

The differential equation of the second order (21) is equivalent to two differential equations of the first order:

$$\begin{aligned} \frac{dy_1}{dr} &= \frac{y_1}{r} + \frac{y_2}{\mu}, \\ \frac{dy_2}{dr} &= \left[(l^2 + l - 2) \frac{\mu}{r^2} - \rho \omega^2 \right] y_1 - \frac{3}{r} y_2. \end{aligned} \quad (22)$$

For spheroidal oscillations, the set of six linear differential equations of the first order is obtained by defining

$$\begin{aligned} y_1 &= U, \quad y_2 = (\lambda + 2\mu) \frac{dU}{dr} + \frac{2\lambda}{r} U - \lambda \frac{l(l+1)}{r} V, \\ y_3 &= V, \quad y_4 = \mu \left[\frac{1}{r} (U - V) + \frac{dV}{dr} \right], \\ y_5 &= P, \quad y_6 = \frac{dP}{dr} - 4\pi G \rho U. \end{aligned} \quad (23)$$

In the case of the liquid core, $\mu = y_4 = 0$ and

$$y_3 = \frac{1}{r\omega^2} \left(g y_1 - \frac{y_2}{\rho} - y_5 \right). \quad (24)$$

Explicit expressions for the elements of the matrix $A(r)$ have been given by Singh (1992).

Equation (20) subject to an appropriate set of homogeneous boundary conditions can be integrated by the Runge-Kutta method. For a given SNREI Earth mode $\lambda(r)$, $\mu(r)$, and $\rho(r)$ and given l , there is a discrete set of values of ω for which the boundary conditions are satisfied. We denote this set by ω_i (eigenfrequencies) and the corresponding displacements by $\mathbf{u}_i$. The index i signifies the normal mode. Each i stands for a triplet (l, m, n) of numbers; l being the colatitudinal mode number, also known as the angular order ($l \geq 0$), m the azimuthal mode number ($-l \leq m \leq l$), and n the

Free Oscillations of the Earth, Table 3 Value of the number N indicating the order of the differential system

Oscillations	Medium	Gravity	N

Spheroidal	Solid	No	4
Spheroidal	Liquid	No	2
Radial	Solid	Yes	2

radial mode number ($n \geq 0$). The numbers l, m, n describe the manner in which the displacement field depends upon the colatitude, the azimuth, and the radial distance, respectively. However, because of the spherical symmetry, the eigenfrequencies are degenerate in m (i.e., ω_l are independent of m). This degeneracy is removed when the rotation of the Earth, its ellipticity, or lateral heterogeneity is taken into account.

The spherical harmonic

$$P_l^m(\cos \theta)(\cos m\phi, \sin m\phi)$$

from which the eigenfunctions are derived has $(l - |m|)$ nodal latitude lines and $2|m|$ nodal longitude lines on the surface of the Earth. The value of m depends upon the source exciting the oscillations.

Table 4 compares the eigenfrequencies computed for PREM (Preliminary reference Earth model (Dziewonski and Anderson 1981)) with mean observed frequencies. The computed eigenfrequencies are obtained from the website (<http://stuplots.geophys.uni-stuttgart.de/~plots/Modes/modes.html>). In this website, the eigenfrequencies and eigenfunctions can be computed for PREM and three other Earth models for $0 \leq n < 50$, $0 \leq l < 200$, using the FORTRAN program MINOS written by Drs. Freeman Gilbert and Guy Masters. The mean observed frequencies are taken from the website (<http://igppweb.ucsd.edu/~gabi/rem.dir/surface/rem.surf.html>). The agreement between the computed and observed values is excellent.

The eigenfrequencies of the toroidal oscillations computed for PREM are shown in Fig. 1 as functions of the angular order l for the fundamental mode $n = 0$ and the first five

overtones $n = 1-5$. The corresponding eigenfrequencies of the spheroidal oscillations are shown in Fig. 2.

Effect of the Rotation of the Earth

As mentioned earlier, the eigenfrequencies of a spherically symmetric, nonrotating, elastic, isotropic Earth model are degenerate in the azimuthal mode number m . The introduction of the rotation removes this degeneracy. The effect of the diurnal rotation of the Earth can be calculated by carrying out a first-order perturbation calculation. Let Ω denote the uniform angular velocity of the Earth about its center. Assume that the observer is referred to a non-inertial frame, which, for all times, maintains a state of uniform rotation with angular velocity Ω . Let (x_1, x_2, x_3) be a Cartesian coordinate system in this uniformly rotating frame of reference, let the origin of the system coincide with the center of the Earth, and let e_3 be aligned along the axis of rotation, so that $\Omega = \Omega e_3$.

The rotation of the Earth introduces two body forces. One of them is the centrifugal force $r \sin\theta \Omega^2$ perpendicular to and away from the axis of rotation. The other force introduced by the rotation is the Coriolis force, which, per unit mass, is equal to $2\Omega(\partial \mathbf{u}/\partial t) \times e_3$.

Assuming $\Omega/\omega_l \ll 1$ (the highest value of $\Omega/\omega_l \simeq 1/27$) and carrying out a first-order perturbation calculation, it can be shown that (Ben-Menahem and Singh 1981, p. 390)

$${}_n\omega_l^m = {}_n\omega_l + m\tau\Omega, \quad -l \leq m \leq l, \quad (25)$$

where

Free Oscillations of the Earth, Table 4 Fundamental mode ($n = 0$) eigenfrequencies ($f = 1/T = \omega/2\pi$), in mHz (10^{-3} cycles per second), for PREM (Preliminary reference Earth model). The corresponding mean observed frequencies are also shown

Free Oscillations of the Earth,**Fig. 1** Eigenfrequency $f = 1/T = \omega/2\pi$ of the toroidal oscillations for PREM**Free Oscillations of the Earth,****Fig. 2** Eigenfrequency of the spheroidal oscillations for PREM. Only points corresponding to even values of $l = 2, 4, \dots, 30$ have been plotted. For the sake of clarity, points representing the eigenfrequencies for even values of l have been joined by continuous curves. However, the intervening curves do not represent any physical reality

${}_n\omega_l$ = eigenfrequencies of a nonrotating Earth model,
 ${}_n\omega_l^m$ = eigenfrequencies of the corresponding rotating Earth model.

The splitting parameter

$$\tau = \frac{1}{l(l+1)} \quad (26)$$

for the toroidal oscillations, and

$$\tau = \frac{\int_0^a (2U + V)V\rho r^2 dr}{\int_0^a [U^2 + l(l+1)V^2]\rho r^2 dr} \quad (27)$$

for the spheroidal oscillations, where a is the radius of the Earth; U and V are defined in Eq. (19).

Therefore, for both toroidal and spheroidal oscillations, the degenerate eigenfrequency ${}_n\omega_l$ is resolved by a slow rotation of the Earth into $(2l+1)$ frequencies ${}_n\omega_l^m$ ($-l \leq m \leq l$). The set of $(2l+1)$ spectral lines for a given (l, n) is called a mode multiplet, and each member of this set is called a singlet. For the toroidal oscillations, the splitting parameter $[l(l+1)]^{-1}$ does not depend upon the Earth model. However, in the case of the spheroidal oscillations, τ depends upon the Earth model. The splitting of the terrestrial spectral lines is the elastodynamic analogy of the splitting of atomic spectral lines by a magnetic field discovered by Zeeman in 1896.

Free Oscillations of the Earth, Fig. 3 Fourier spectrum of the 27 February 2010 Maule (Chile) earthquake ($M_w = 8.8$) record provided by the superconducting gravimeter at the Black Forest Observatory (BFO). The rotation removes the degeneracy and splits the ${}_0S_3$ multiplet into seven singlets. The vertical dashed lines indicate the theoretically predicted

frequencies of the singlets for the spherically symmetric Earth model PREM, including the effect of the rotation of the Earth and hydrostatic flattening. (Figure made available by Dr. Rudolf Widmer-Schmidrig of BFO who holds the copyright)

Figure 3 shows the Zeeman splitting of the fundamental spheroidal mode of the third-order ${}_0S_3$ observed in the Fourier spectrum of the gravimeter record of the 27 February 2010 Maule (Chile) earthquake. The time series is 400 h long, and the effect of local barometric fluctuations has been removed. The rotation of the Earth removes the degeneracy of the multiplet; six out of seven singlets can be clearly identified. The singlet corresponding to the azimuthal mode number $m = 0$ is missing because either the source or the receiver is located on a nodal line of the mode.

The ellipticity of the Earth also removes the degeneracy giving (Dahlen 1968)

$${}_n\omega_l^m = {}_n\omega_l [1 + e(b + m^2c)] \quad (28)$$

to first order in ellipticity e , where $b = b(n, l)$, $c = c(n, l)$. Thus the ellipticity splits the degenerate eigenfrequency ${}_n\omega_l$ into $(l + 1)$ lines ${}_n\omega_l^m$ ($0 \leq m \leq l$).

Other departures from symmetry, e.g., lateral inhomogeneity, anisotropy, and initial stress, have the same effect of removing the degeneracy.

Jeans' Formula

The complete seismic field induced by a point source in an SNREI Earth model can be expressed as an infinite sum of normal modes. However, we know from seismogram analysis that most of the recorded Earth motion can be explained in terms of propagating waves. Therefore, there must exist a relationship between these two seemingly different aspects of seismic wave motion.

Consider a general term in the normal-mode solution expressed by Eqs. (18) and (19). The factor of this term which depends upon the time and the colatitude is derivable from

$$P_l^m(\cos \theta) \exp(i\omega t), \quad (29)$$

where $\omega = {}_n\omega_l$ is an eigenfrequency. Replacing the Legendre function by its asymptotic approximation for large values of l , this factor becomes

$$(-l)^m \left(\frac{1}{2\pi l \sin \theta} \right)^{1/2} \left[\exp \left\{ i \left[\omega t - (l + 1/2)\theta + \frac{\pi}{4} - \frac{m\pi}{2} \right] \right\} + \exp \left\{ i \left[\omega t + (l + 1/2)\theta - \frac{\pi}{4} + \frac{m\pi}{2} \right] \right\} \right]. \quad (30)$$

The first term describes a wave motion of frequency ω diverging from the pole $\theta = 0$, whereas the second term describes a wave motion diverging from the antipode $\theta = \pi$.

In cylindrical coordinates, a wave diverging from the axis may be expressed in the form

$$\exp[i(\omega t - k\Delta)], \quad (31)$$

where k is the wave number. Putting $\Delta = a\theta$ and comparing Eqs. (30) and (31), we get Jeans' formula (Jeans 1923):

$$l + \frac{1}{2} = ka \quad (l \gg 1).$$

This formula tells us that, if l is large, every mode of oscillation can be interpreted as a travelling wave whose parameters are functions of l and n and are given by

$$T = \frac{2\pi}{\omega}, c = \frac{a\omega}{l + \frac{1}{2}}, \Lambda = \frac{2\pi a}{l + \frac{1}{2}}, \quad (32)$$

where T is the period of the oscillation, c is the phase velocity, and Λ is the associated wavelength. These relations are found to yield a good approximation for $l \geq 7$. The connection between the free oscillations and travelling waves (mode-ray duality) has been studied by Jeans (1923), Ben-Menahem (1964), Brune (1964), and others.

Jeans formula can be used to determine the eigenfrequencies from the observed dispersion data, and then the normal-mode formalism can be used to find the elastic properties of the Earth.

Continuous Free Oscillations of the Earth

Free oscillations of the Earth are typically observed after a large earthquake. Continuous free oscillations of the Earth (primarily fundamental spheroidal modes between 2 and 7 mHz) were discovered in 1998 (Suda et al. 1998; Tanimoto 2001). Observational evidence points to the atmosphere (e.g., Kobayashi and Nishida 1998) and oceans (e.g., Rhie and Romanowicz 2004) as possible sources of excitation of these oscillations. Stochastic excitation of normal modes by surface pressure variations, caused by atmospheric and/or oceanic turbulence, may explain the overall amplitudes of their observed modes. Since the discovery of the continuous free oscillations of the Earth, also known as seismic hum, in 1998, a large number of geophysicists got interested in their study (see, e.g., Nishida et al. 2000, 2009; Fukao et al. 2002; Tanimoto 2005; Webb 2007). In a recent survey, Nishida (2013) discussed at length the observation of the continuous free oscillations of the Earth and their source of excitation. According to Nishida (2013), Earth's background free oscillations from 2 to 20 mHz are observed at globally distributed stations, excited modes of these oscillations are almost exclusively fundamental spheroidal and toroidal, and amplitudes of the toroidal modes are larger than those of the spheroidal ones.

Conclusions

We have described how to compute the eigenperiods of an SNREI Earth model. Modifications due to lateral inhomogeneity, anisotropy, and initial stress can be found by perturbation methods (Woodhouse and Dahlen 1978). The eigenperiods of different modes of vibration are increased by the anelasticity of the Earth. In addition, anelasticity results

in the decay of the amplitudes of the free oscillations with time. Necessary allowance for anelasticity can be made while constructing Earth models using normal-mode theory (Dziewonski and Anderson 1981).

The study of the free oscillations of the Earth has played a leading role in the development of geophysical inverse theory in the late 1960s (Backus and Gilbert 1967, 1968, 1970) and 1970s. This theory enables us optimal extraction of information regarding the internal constitution of the Earth from a finite set of gross Earth data (Wiggins 1972). Comprehensive exposition of the inverse theory has been given, among others, by Tarantola (1987) and Parker (1994). Dahlen and Tromp (1998) gave a comprehensive treatment of the problem of computing synthetic seismograms for a realistic three-dimensional model of the Earth, using normal-mode summation technique. In their recent review, Woodhouse and Deuss (2015) gave a detailed account of the theory and observations of the free oscillations of the Earth.

Major discoveries based on the observations of the Earth's free oscillations are (in chronological order):

1. Finite rigidity of the inner core (Dziewonski and Gilbert 1971)
2. 1D density distribution inside the Earth (Gilbert and Dziewonski 1975; Masters and Gubbins 2003)
3. Construction of PREM (Preliminary reference Earth model) by Dziewonski and Anderson (1981)
4. Construction of the first global 3D upper mantle velocity model (Masters et al. 1982)
5. Construction of 1D attenuation model (e.g., Masters and Gilbert 1983)
6. Tight upper bound on the maximum differential super rotation of the inner core (e.g., Laske and Masters 1999)
7. Regional variation of inner core anisotropy (e.g., Deuss et al. 2010)

Geodesy, Figure of the Earth

Kusumita Arora

National Geophysical Research Institute, Council of Scientific and Industrial Research (CSIR), Hyderabad, India

Definition

Geodesy is the discipline that deals with the measurement and representation of the Earth, its gravity field, and geodynamic phenomena (polar motion, Earth tides, and crustal motion) in three-dimensional time varying space.

“Figure of the Earth” in geodesy deals with the representation of the external geometry of the whole planet often also called physical geodesy, without going into the causal mechanisms. On the other hand, engineering geodesy is concerned with measuring specific parts or regions of Earth, which contribute to understanding of geophysical measurements and in turn to geodynamic processes. This article provides a brief description of the former.

Background

The shape of the Earth has always been speculated upon – historical accounts of sailors record that they feared falling off the edge of the Earth if they sailed too far. Early ideas about the figure of the Earth held the Earth to be flat and the heavens a physical dome spanning over it. Two early arguments for a spherical Earth were that lunar eclipses were seen as circular shadows which could only be caused by a spherical Earth, and that the pole star is seen lower in the sky as one travels south.

The flat disc advocated by Homer (in the ninth century B.C.) later gave way to the spherical body postulated by Pythagoras (in the sixth century B.C.) – an idea supported one hundred years later by Aristotle (384–322 B.C.). According to old texts, the first geodetic experiment took place around

250 B.C. by Eratosthenes (about 284–192 B.C.) in Egypt. Eratosthenes noted that the Sun on the summer solstice day at Syene (close today to Assouan) was at the zenith while its zenithal distance at Alexandria (approximately on the same meridian) was recorded as $7^{\circ}12'$. By knowing the geometrical distance between Syene and Alexandria thanks to a cadastre performed by Ptolemy Soter (about 360–283 B.C.), he deduced, the length of the terrestrial circumference as 40,500 km. Later Hipparchus (in the second century B.C.) recommended the use of latitudes and longitudes for cartography (in agreement with its Greek etymology). The great Indian mathematician Aryabhatta (476–550 A.D.) described the Earth as being spherical and rotating on its axis. He estimated the circumference of the Earth, accurate to 1% of today’s measurement. The medieval Persian geodesist Abu Rayhan Biruni (973–1048 A.D.) is sometimes regarded as the “father of geodesy” for his significant contributions to the field. He solved complex geodesic equations based on spherical trigonometry in order to accurately compute the Earth’s circumference and radius, which are very close to modern values.

The shape of the Earth is the combined result of the forces due to the various motions, rotation being the strongest under the influence of gravity including its spatiotemporal variations as well as horizontal tectonic forces (more in ► “[Geodesy, Physical](#)” and ► “[Gravity, Global Models](#)” in this volume).

Mathematical Figures of the Earth

The actual shape of the Earth consisting of its topographic surface with its variety of land forms and water areas is not suitable for mathematical representations because the formulas which would be required to take these features into account would necessitate a prohibitive amount of computations. The Pythagorean concept of a spherical Earth offers a simple surface, which is mathematically easy to deal with. Many astronomical and navigational computations use it as a surface representing the Earth. While the sphere is a close

approximation of the true figure of the Earth and satisfactory for many purposes, to the geodesists interested in the measurement of long distances – spanning continents and oceans – a more exact figure is necessary. In the mid- to late- twentieth century, research across the geosciences contributed to drastic improvements in the accuracy in the description of the Figure of the Earth.

The concept of a perfectly spherical Earth was eventually refined by Sir Isaac Newton based on his theory of gravity, deriving that the Earth would not be perfectly spherical but slightly squashed at the poles and bulging at the Equator due to the forces acting upon it as it spins. Mathematically this shape is described as an oblate spheroid or as an ellipsoid of revolution (Fig. 1), an oval that revolves about its shortest dimension. This shape is most commonly used for measurements over long distances, across continents or oceans. Closer approximations utilize spherical harmonics for whole Earth shape or local approximations in terms of local reference ellipsoids. An equipotential ellipsoid is an ellipsoid that is defined to be an equipotential surface of normal gravity potential, determined by means of the ellipsoidal surface, the enclosed mass, and the angular velocity (independently of the internal density distribution). The equipotential ellipsoid furnishes a simple, consistent, and uniform reference system for all purposes of geodesy and does not include an atmosphere (more in ► “Geodesy, Physical”, ► “Gravity, Global Models”, and ► “Gravity Method, Satellite” in this volume).

Another method estimates the Earth’s surface using mean sea level of the ocean with all continents removed – this surface is equivalent to an equipotential surface and is called the Geoid. Due to variations in the Earth’s mass distribution (oceans and land), the Geoid has an irregular shape that is described as “undulating.” The ellipsoid of revolution mentioned above is a mathematical approximation of the Geoid. The Geoid, unlike the ellipsoid, is too complicated so far to

Geodesy, Figure of the Earth, Fig. 1 An oblate spheroid (black) superimposed on sphere (cyan), R_p is the polar radius 6357 km, and R_E is the equatorial radius 6378 km. θ is the latitudinal angle

serve as the computational surface on which to solve geometrical problems like point position. The separations between the two, referred to as Geoid undulations, Geoid heights, or Geoid separations, are irregular. The Geoid undulations over a spherical Earth are shown in Fig. 2, where the red colored areas indicate positive deviations of the Geoids from the ellipsoid and the blues indicate negative deviations of the Geoids from the ellipsoid. Many of these deviations have obvious spatial correlations with surface expressions of substantial topographic features, which in turn indicate significant geodynamic activity. However, there are also undulations, which do not bear such relations; their causal mechanisms remain to be established (more in ► “Geoid Undulation, Interpretation” in this volume). With the availability of decades of highly accurate, consistent, uniform data of gravitational measurements from satellites along with the data from an increasing number of GNSS satellites, the accuracy of geoid computations has reached new heights (more in ► “GPS, Tectonic Geodesy” in this volume).

Since the last several decades, geodetic satellites using precise orbit computation determine the global geoid. Changes of geoid undulations and gravity anomalies on the Earth’s surface are determined from the moments of satellite orbits. EIGEN-1S, based on GPS satellite-to-satellite tracking and accelerometer data from CHAMP satellite produces a geoid with an approximation error of about 20 cm in terms of 5×5 degree block mean values, which is made possible because of CHAMP’s tailored orbit characteristics and dedicated instrumentation, providing continuous tracking and direct on-orbit measurements of nongravitational satellite accelerations (Reigber et al. 2002). The AUSGeoid2020 is a combined gravimetric-geometric model. The gravimetric component is a $1'$ by $1'$ grid based on data from gravity satellite missions (e.g., GRACE, GOCE), localized airborne and land gravity data. The geometric component is a $1'$ by $1'$ grid of quasigeoid-height separation values and is developed using a dataset of collocated GNSS ellipsoidal height and Australian Height Datum heights (<http://www.ga.gov.au/ausgeoid/>).

Apart from rotation, there are other motional forces, which affect the shape of the equipotential surface. Precession is the effect of external torque exerted on the Geoid causing the spin axis to describe a circular cone. This motion is caused by the gravitational attraction of other celestial masses, particularly the sun, moon, and planets. Precession arises because of the ellipticity of the Geoid, with torque exerted on the equatorial bulge, in combination with the obliquity of the axis of rotation in relation to the plane of revolution (the ecliptic and fixed, heliocentric space). The period of precession is presently about 25,780 years.

Polar Motion is the change in the position of the axis of rotation in relation to the surface of the Geoids, which was observed by five stations near latitude 39.1333° N, which began latitude observations in 1899. The Conventional

Geodesy, Figure of the Earth,

Fig. 2 Geoid undulations derived from observed gravitational satellite orbit perturbations (from <https://cddis.nasa.gov/926/egm96/egm96.html>). The greatest departure of the geoid from ellipsoidal form is a 105-m low south of India. This is very small compared with undulations of the land surfaces or the 5-km mean difference in level between continents and ocean floors

International Origin is defined as the mean position of the instantaneous pole during the period 1900–1905. Secular Polar Motion, quantified by astrometric and geodetic measurements as well as those of GNSS satellites is the drift in the pole position due to a combination of several forces: glacial isostatic adjustment, Earth's surface mass transport, seismogenic mass exchange, and changes in Earth's inertia tensor by mantle convection (Adhikari et al. 2018). It is a significant component of the Earth's orientation change, which undergoes variations on time scales from subdaily to decadal and longer.

Determining the exact figure of the Earth involves both surface geometry as well as geophysics. Without any idea of the Earth's interior, we can state a “constant density” of 5.515 g/cm^3 , and according to theoretical arguments such a body rotating like the Earth would have a flattening of 1:230. In fact, the measured flattening is 1:298.25, which is more similar to a sphere and a strong argument in favor of very compact Earth's core. Therefore, the density must be a function of the depth, reaching from about 2.7 g/cm^3 at the surface to approximately 15 g/cm^3 within the inner core. With increasing accuracy of the measured global gravity field from dedicated satellite missions, it is observed that the true vertical generally does not correspond to the theoretical vertical (deflection ranges from $2''$ to $50''$) because topography and all geological masses disturb the gravitational field. Therefore, the gross structure of the Earth's crust and mantle can be determined by geodetic-geophysical models of the subsurface (more in ► “Geodesy, Physical”, ► “Geoid”, ► “Gravity, Global Models”, and ► “Gravity Method, Satellite” in this volume).

Reference Coordinate System

Description of the shape and size of the Earth as well as measurement of distances on its surfaces and definitions of

position locations of any particular point inevitably depends upon the use of a Reference Coordinate System. Reference ellipsoids are customarily expressed by the size of the semi-major axis (a) and flattening (f). The quantity f is a purely mathematical one. The mechanical ellipticity of the Earth (dynamical flattening) is determined by observation and differs from the geometrical because the Earth is not of uniform density. The 1967 Geodetic Reference System posited a 6,378,160 m semimajor axis and 1:298.247 flattening. The 1980 Geodetic Reference System posited a 6,378,137 m semimajor axis and 1:298.257 flattening. This system was adopted at the XVII General Assembly of the International Union of Geodesy and Geophysics (IUGG).

The World Geodetic System 84 (WGS-84) is a standard for use in cartography, geodesy, and navigation. It comprises a standard coordinate frame for the Earth, a standard spheroidal reference surface (the *datum* or *reference ellipsoid*) for raw altitude data, and a gravitational equipotential surface (the *Geoid*) that defines the *nominal sea level*. Presently, WGS 84 uses the 1996 Earth Gravitational Model (EGM96) Geoid, revised in 2004. This Geoid defines the nominal sea level surface by means of a spherical harmonics series of degree 360 (which provides about 100 km horizontal resolution). The deviations of the EGM96 Geoid from the WGS 84 reference ellipsoid range from about -105 m to about $+85 \text{ m}$.

International Terrestrial Reference System (ITRS) was defined by the IUGG in 1991 as a geocentric nonrotating system identical to the International Astronomical Union (IAU) defined Geocentric Reference System with Geocentric Coordinate Time (TCG). Conventional Terrestrial System (CT) is geocentric and references north to the 1900–1905 mean pole and 0° longitude to Greenwich Observatory. Terrestrial coordinate systems are Earth-fixed and spin and revolve with the Earth. Terrestrial Reference System (TRS) is a spatial reference system co-rotating with the Earth in space, with positions of points attached to the solid surface of the Earth

having coordinates which undergo only small variations with time, due to geophysical, tectonic, or tidal deformations.

Nowadays, the realizations of the fundamental reference system supported by the International Association of Geodesy, the ITRF (International Terrestrial Reference Frame with the year of realization, at present the ITRF 2008) are very strongly recommended to be only used in precise geodesy for geosciences applications and for navigation satellite systems. Fortunately, the choice of fundamental parameters of WGS 84 was to be made in the beginning (in the 80s of last century) as close as possible to the ITRF (at this time defined by the BIH – the Bureau International de l’Heure). As a result, within 1 m there is no difference between what is defined as WGS 84 and the ITRF 2008, the latest international realization with a centimeter level of accuracy (more in ► “Geodesy, Ground Positioning, and Levelling” and ► “Geodesy, Networks, and Reference Systems” in this volume).

Datum

A datum is a framework that enables us to define coordinate systems. Definition of datum has improved considerably with advancements in measurement techniques through technology.

Traditional Geodetic Datum: To describe positions on the Earth accurately, traditionally two datum were required; a horizontal datum and a vertical datum.

Horizontal Datum: A horizontal datum is used to fix a position in the X and Y directions. A horizontal datum was traditionally defined using an ellipsoid and an origin. The ellipsoid was generally chosen for a best fit of the Geoid locally.

Vertical Datum: A Vertical Datum is used to fix a position in the vertical direction, up and down the Z axis. A vertical datum is a line, value, or set of values from which heights are measured.

The International Terrestrial Reference Frame (ITRF) is defined by the International Terrestrial Reference System and the Datum consistent with it and is based on a number of very accurate observations all over the Earth, employing Very Long Baseline Interferometry (VLBI), Satellite Laser Ranging (SLR), Lunar Laser Ranging (LLR), and the Global Positioning System (GPS) techniques. The measurements relate to a 3D Earth-centered Cartesian coordinate system. In changing to this Geocentric Datum, the Global Positioning System [GPS] can be most effectively used (more in ► “Geodesy, Networks, and Reference Systems” in this volume).

Summary

Geodesy, Figure of the Earth outlines the basic parameters by which the shape of the Earth is defined. The Earth

being a system in dynamic equilibrium is under the influence of many forces, all of which contribute to its final structure and thereby its detailed shape. The subject of Geodesy has evolved sufficiently technologically and mathematically to take into account the details of the Earth’s shape as well as the physics of the causal mechanisms.

Definition

Geodesy	Science for the determination and representation of the figure, shape, and size of the earth and of other celestial bodies along with their external gravity field as a function of time
Positioning	Determination of coordinates for points on earth, sea, or space with respect to a reference system
Ground positioning	Determination of terrestrial coordinates
Levelling	The determination of heights of points with respect to a reference surface

Introduction

Geodesy, along with astronomy, is considered the oldest earth science and dates back to the Sumerians of 5000 years ago. The word “geodesy” is composite and is derived from the Greek noun “Γη = earth” and the verb “δαίω = divide.” It is, literally, the science used to “divide, distribute, and measure the earth.” The roots of geodesy can be found in ancient Egypt and Babylon where “the geometry of the earth” was used for the recovery of the land property boundaries, after, for example, the flooding of crops by the Nile River. The word “geodesy” appeared, for the first time, in the fourth century B.C. in Aristotle’s book *Metaphysika*. Before Aristotle, “geodesy” was called the “geometry of the earth.” Ancient Greeks and Romans were the first to invent geodetic or *surveying* instruments for constructing roads, buildings, and tunnels, laying water pipes and culverts, land surveying, etc. Great scientists such as Pythagoras, Aristotle, Eratosthenes, Poseidonius, W. Snellius, J. Picard, Newton, Gauss, Cassini, and many others contributed to geodesy, surveying, high-precision levelling, and mapping.

Today, *geodesy* is the science of accurately measuring and understanding (1) the geometric size, shape, and orientation of the earth, (2) its gravitational field, and (3) the variations of these quantities over time (Torge and Müller 2014; Herring 2009). The development of geodesy goes together with spectacular achievements in the fields of astronomy, mathematics,

probability and statistics, physics, map projections, fast computing, etc. As a first approximation, “geodesy” can be considered as the science of measuring distances or heights between terrestrial objects or measuring angles between lines and determining directions of lines for the establishment of coordinates of points on or near the earth’s surface. This is also called *ground positioning* or *surveying*.

One of the main tasks of geodesy is *positioning*. This is the accurate determination of coordinates of points on the earth’s surface, at sea, or in space with respect to a reference system (Petit and Lusum 2010). Positioning can be divided into *absolute positioning*, where coordinates are determined with respect to an inertial reference system, and into *relative positioning* when coordinates are derived with respect to other reference points on earth. Positioning constitutes essential information for mapping, cadastral surveys, highway and dam construction, earthquake and landslide monitoring, geodetic control networks, crustal and structural deformation, etc.

Ground positioning has traditionally been carried out using measurements of distances and angles (and or directions) between terrestrial lines with theodolites and measuring tapes (Anderson and Mikhail 1997; Kavanagh and Mastin 2013). Later, distances have been measured by other equipment using the electromagnetic radiation. Over the last two decades, the methods and instruments for measuring, acquiring, storing, calculating, reducing, and portraying geodetic ground positioning data have changed dramatically. New types of geodetic measurements, along with the traditional ones, are now being made with total electronic geodetic stations, terrestrial laser systems, inertial systems, ground-based radar interferometers, terrestrial wireless positioning systems, precise underwater positioning systems, and finally the space-based systems such as the global navigation satellite systems (Kaplan and Hegarty 2017).

Geodetic levelling is the precise determination of height difference between two or more points on the earth’s surface. It ultimately aims at the determination of the height above a reference surface, usually the mean sea surface. Again in levelling, the ancient Egyptians and the Babylonians were the first to employ it to connect the Nile River with the Red Sea and to apply levelling for irrigation. In the following sections, the geodetic ground positioning and levelling will be briefly elaborated.

Ground Positioning

The primary purpose of ground positioning is to provide coordinates of points on the earth’s surface based on either (1) the astronomic determination of latitude, longitude, and azimuth of a terrestrial line or (2) the observation of horizontal angles, distances, zenith angles, and height differences.

A *horizontal angle* is defined as that angle measured in the horizontal plane of the observer between two vertical planes. The *horizontal plane* is the tangent plane to the equipotential surface of the gravity field at the point of observation. In early geodetic surveys, painstaking efforts were employed to accurately measure angles and distances. Angles were – and are still to this day – measured using theodolites, and the distances were measured using tapes made from metal having a low coefficient of thermal expansion. Later, electronic instruments were used for measuring angles and distances.

Electromagnetic distance measuring devices have been used to determine the distance between geodetic stations on the ground. Electromagnetic pulses are transmitted to a retro-reflector (or even to the terrain target), and the emitted signal finally returns to the instrument. Intervisibility requirements and attenuation of the signal, mainly due to the atmosphere, allow measurements to be made at ranges up to about 50 km; but the best results are obtained at shorter distances with an accuracy even higher than 0.1 to 0.3 mm over 100 meters.

Point coordinates have thus been established by a process of triangulation, trilateration, or traverse surveys. *Triangulation* is the process of determining the relative positions of a

network of *control points* (Kavanagh and Mastin 2013) on the ground by theodolite measurements of directions or angles between intervisible stations (Fig. 1). Angles have been more easily measured, as compared to distances, particularly when large distances over mountainous and rugged terrain were involved. As the name implies, triangulation employs horizontal angles and a limited number of lengths – called *geodetic baselines* – of connected triangles to determine trigonometrically the positions of stations (vertices of triangles). Triangles have been the simplest geometric figure which permit rigorous checks and adjustments of field observational errors. To compensate for the errors in the measurements, triangulation networks are adjusted mainly using the method of least squares. This method not only yields the final and adjusted coordinates of the vertices of the triangles but also gives their coordinate accuracies (Ghilani 2017).

Trilateration is similar to triangulation process and again aims at the relative determination of positions using triangles but now with their lengths measured by electromagnetic radiation with electronic instruments (Fig. 2). Finally, *traverse surveys* consist of measurements of both horizontal (and vertical) angles at the traverse stations and distances

Geodesy, Ground Positioning, and Levelling, Fig. 1

An example of a triangulation network. The baseline AB is either known or measured, while all angles in the formed triangles are observed

Known parameters:

1. Geodetic baseline AB (distance is known),
2. Latitude and Longitude of stations A και B,
3. Azimuth of length AB.

Measurements:

All horizontal angles to visible stations.

What is finally computed:

1. Distances to all control stations (triangle vertices),
2. Latitude and longitude of all stations,
3. Azimuth of all lines.

Geodesy, Ground Positioning, and Levelling, Fig. 2

A trilateration network where the azimuth of the baseline AB is determined to orient the network with respect to the north and all sides of the formed triangles are observed

**Known parameters:**

1. Geodetic baseline AB,
2. Latitude and longitude of stations A and B,
3. Azimuth of line AB.

Measurements:

All distances to all inter-visible sites (stations).

What is finally computed:

1. Angles and distances for all formed triangles,
2. Latitude and longitude for all stations,
3. Azimuth of all lines.

along a series of connected lines on the ground. Unlike triangulation and trilateration, in which stations are commonly widely separated (e.g., 20–60 km), traverse surveys generally follow routes of highways, railways, etc., with stations located close together (i.e., a few hundred of meters). The coordinates of these traverse stations are computed using basic trigonometric expressions as shown in Fig. 3.

Astronomic azimuths are used to determine the orientation of the network with respect to the ellipsoid. The *astronomic azimuth* is the angle in the observer's local horizontal plane between the astronomic meridian and the vertical plane passing through the target point. Two coordinates, the geodetic latitude and longitude of each station of the network, are then computed on this ellipsoid. The third coordinate of *height* above the reference ellipsoid is determined either from levelling and gravity data or from vertical angles.

All these geodetic measurements as well as other types (e.g., distance differences) are being made, today, by total geodetic stations, terrestrial laser systems, inertial systems, ground-based radar interferometry, wireless positioning, etc.

New kinds of theodolite measurement systems do not require a target and/or reflector to be monitored. They are

able to measure point coordinates without targeting the object to be observed (Reiterer et al. 2007). Such systems use the texture on the terrestrial surface or of an object to locate “points of interest” to make angle and distance measurements. However, these new instruments require well-trained personnel to operate them.

Terrestrial laser scanners (Parker 2019) can also provide detailed and highly accurate three-dimensional coordinates of terrestrial points rapidly and efficiently. Some scanners are suitable for indoor use and medium ranges (up to 100 m), while others are better for outdoor applications with longer ranges. Most systems use a laser beam, emitted by the instrument, which is directed into different directions, through a mechanical deflection mirror, to a number of reflective surfaces on the ground. The deflected laser light is detected, and the instrument measures the time of flight for long ranges and the phase measurement of the reflected signal for medium ranges. For various scanning rates and/or a vertical scan angles up to 90°, the deflection mirror rotates continuously at adjustable speed and records target *range*, *angle*, *signal amplitude*, and *time*. Some terrestrial laser scanners incorporate a camera to also capture a picture of an object being

Geodesy, Ground Positioning, and Levelling, Fig. 3

An example of a closed traverse. The geographic coordinates as well as the azimuth of the initial point A, with respect to point B, are known. Then the exterior (or interior) angles at each traverse station are observed along with the interstation distances. The Cartesian coordinates for all stations of the traverse and the azimuths for all lines are determined using trigonometry

Known parameters:

1. Latitude and longitude of point A ,
2. Azimuth of line AB.

Measurements:

1. The distances between all traverse stations
2. Interior angles at each traverse station.

What is finally determined:

1. Cartesian coordinates for all stations,
2. Azimuth for all lines in the traverse.

scanned. The accuracy of distance measurements is of the order of ± 1 cm (± 1 mm over 10 m), but this primarily depends on the intensity of the reflected laser light and on the reflectivity of the target surface. Terrestrial laser scanners have been used to characterize the kinematics of the landslide ground surface, by evaluating the involved displacement and deformation patterns. They have also been applied in surveying, mining, construction surveying, architecture, archaeology applications, deformation monitoring, etc.

The standard wireless (i.e., Wi-Fi and the ultra-wide band) networks employ a number of transmitters on the ground and not only provide a way for finding the optimum communication relay routes in an ad hoc network of transmitters but are also capable for ground positioning. The locations of the communication nodes (i.e., transmitters) of these networks are known. Positioning is achieved by measuring the *time of arrival* and the *time difference of arrival* for the communication signals. Thus, the positional accuracy of a network user

depends of the ranging errors, the connectivity, and the available number of mobile nodes. The developed ultra-wide band systems provide a dynamic three-dimensional accuracy of better than 5 mm (Zuin et al. 2018). They are, at present, used for indoor wireless positioning, including robot tracking and monitoring, but future uses to geophysical applications are soon to emerge.

Geodetic positioning techniques have also been extended to underwater applications using acoustic ranging to measure crustal deformation with cm level accuracies at several thousand of meters depths (Gagnon et al. 2005; DeSanto et al. 2016).

Another promising technique for geodetic positioning, height mapping, and deformation monitoring, such as tectonic seismic and volcanic deformation as well as ice and rock-glacier motion and ground subsidence, is provided by the *ground-based interferometric radar systems* (Werner et al. 2008; de Macedo et al. 2017). These instruments use real

Geodesy, Ground Positioning, and Levelling, Fig. 4 A ground-based interferometric radar system to monitor deformation

aperture radar antennas to illuminate a target area on the ground (Fig. 4). The antennas are mounted in parallel on a rotational scanner. A radar image of the target area is formed, line by line, by rotating the antennas in azimuth and in the vertical axis. The range and the azimuth resolution of these radars are determined by the antenna beamwidth and the slant range. *Phase differences* (Cumming and Wong 2005) between successive images, acquired from the same viewpoint, are used to determine line-of-sight displacements better than 1 mm. These instruments are used for monitoring rapid moving landslides, and unstable mine slopes, as well as for terrain mapping. They can be used for short ranges from sensor to target (up to 1000 m) to medium-range applications (up to 4 km). The resulted accuracies are of the order of ± 1 mm, and the entire observed area can reach up to thousands of square meters, while the radar system measures the displacements of all points in the area illuminated by the antenna.

Finally, space geodetic techniques are based on processing signals received from earth-orbiting satellites to provide precise ground positioning and levelling (Herring 2009; Teunissen and Montenbruck 2017). These systems, called global navigation satellite systems (GNSS), include the US Global Positioning System (GPS), the Russian Global Navigation Satellite System (GLONASS), the European Galileo, the Chinese BeiDou, the Indian Gagan, the Japanese Quasi-Zenith Satellite System, etc. Although originally developed for military and navigational purposes, new measuring and processing techniques (Hofmann-Wellenhof et al. 2007; Leick 2003; Teunissen and Montenbruck 2017) were

developed to improve the originally designed positioning accuracy of several meters. Today, these systems provide coordinates of ground locations at the mm level in the horizontal as well as in the vertical sense (Blewitt 2010) over larger distances of several tens or hundreds of kilometers. In addition, they allow for three-dimensional positioning and do not require interstation visibility, their accuracy does not degrade with distance significantly, and they provide continuous (e.g., every 1 or 20 Hz) positioning with respect to a global reference frame. In this vein, they have been applied for mapping, precise ground positioning to monitor plate tectonics, seismic and volcano ground deformation, etc.

The computational process, for all the above geodetic positioning techniques, requires their reduction on a reference surface, usually taken as a flat horizontal surface or the *reference ellipsoid* (Petit and Lusum 2010) (Fig. 5). In the flat horizontal surface, the directions of the plumb line (and thus gravity vector) is considered parallel. The ellipsoid is the curved surface approximating the size and shape of the earth, and the Cartesian coordinate system is usually an earth-centered reference system for three-dimensional computations. Calculations involve solving equations derived from solid geometry, calculus, and statistics (Torge and Müller 2014; Meyer 2010).

The measured angles (directions) and distances are projected along normals onto the reference ellipsoid. The *geodetic datum* (Petit and Lusum 2010) is also defined that enables accurate location of features on earth through a mathematical model that describes the origin, orientation, and scale of coordinate systems.

Geodesy, Ground Positioning, and Levelling, Fig. 5 The observations of angles, distances, etc., measured on the earth's surface are reduced upon a reference ellipsoid and/or a flat horizontal plane

Levelling

Levelling is the general term applied to indicate the process by which elevations of points or differences in elevation between two or more points on the surface of the earth are determined. Differences in elevation are determined by taping, differential levelling, and barometric levelling and indirectly by trigonometric levelling. All height determinations require the establishment of a vertical datum (Sanchez and Sideris 2017), usually taken as the mean sea level. This is realized by relative permanent objects on the ground, called *benchmarks*, whose elevation above an adopted geodetic datum is known.

Differential levelling is accomplished by making measurements to two or more points through a telescope. The instrument's telescope, with suitable magnification, is regularly set horizontally with its line of sight being parallel to the equipotential surface of the local gravity field. A horizontal line of sight is established within the telescope by a level vial or automatic compensator. The basic procedure is illustrated in Fig. 6. A vertical measurement is made to the backsight of a graduated rod, held on fixed points, and is added to its height. Thus the height of the levelling instrument is determined. A second measurement is made to determine the height of the foresight rod. The instruments can then be moved forward, and the levelling process is repeated until the elevation difference between the initial and the final point is established. Levelling procedures are limited by light of sight and to the distance between the level instrument and the rod. The readings on the rod can be taken either optically or electronically; the rod must be close enough to the level (about 40 m) to resolve the rod's readings in order to make

accurate readings. Today, digital levels measure electronically to bar-coded rods, but can also measure optically to conventional rods. These are easy to use, and because heights and distances are recorded electronically, reading and writing errors are avoided. They can be used for precise levelling of flat and sloping surfaces and for establishing the vertical component of grade and ground profiles and for subsidence monitoring and control. The accuracy in height determination is of the order of less than ± 1 mm per km of distance in double levelling.

Differences in elevation are proportional to differences in the atmospheric pressure. Thus barometers, which are instruments to measure atmospheric pressure, can be used to determine relative elevations of points on the earth's surface. Elevations determined by barometric levelling probably are several meters in error even after they are corrected for the effects of temperature and humidity. Barometric measurements are made at a benchmark, while a second roving barometer is carried from point to point in the field.

The difference in elevation between two points can also be established by measuring the vertical angle of the line from one point to the other and then computing the difference in elevation from either the slope distance between the two points. Trigonometric levelling is necessary when the elevations of inaccessible points must be determined. From two points of known position and elevation, the horizontal position of the unknown point is found by triangulation, and the vertical angles from the known points are measured. The technique is influenced by the atmosphere refraction (cloudy weather with good visibility with consistent temperature over measurement) and the earth curvature.

Geodesy, Ground Positioning, and Levelling, Fig. 6 Differential levelling. Two rods are placed vertically on points A and B, where the height difference between them is determined. The instrument is set up in the midway of A and B. A vertical measurement is made to the backsight

of the graduated rod placed at A. A second measurement is also made to the foresight rod at B. The height difference is determined by subtracting the foresight from the backsight reading

Summary

At present, the reference systems upon which all these geodetic positioning and levelling techniques are based have been well defined with unprecedented accuracy and reliability (Petit and Lusum 2010; Sanchez and Sideris 2017). The theory of errors for geodetic positioning and levelling has been well developed and applied in the measurements made. New data collection and processing technologies have emerged and matured. So, better results and reliable results are obtained, while the burden of adjustment computation

and efficiency has further improved with fast computing and improved measurements and processing algorithms. All in all, geodesy, ground positioning, and levelling have seen tremendous developments in recent years. New measurements (from optical to electronic) and new techniques (from angle measurement to phase and time and time-difference measurement of electromagnetic signals) and new instrumentation with increased accuracy (from meters to cm and mm at long distances) and capabilities (integration with Geographic Information Systems) have been emerged and matured for geophysical applications.

Geodesy, Networks, and Reference Systems

Hayo Hase

Geodätisches Observatorium Wettzell, Bundesamt für Kartographie und Geodäsie, Bad Kötzing, Germany

Definition

Geodesy	Scientific discipline dealing with the measuring and representing of Earth in the domains of time, space, and the gravitational field.
Networks	Set of materialized geodetic reference points as carriers of a specific reference frame tied to each other by geodetic measurements.
Reference system	A reference system is based on one definition of the reference. A geodetic reference system is a definition of a specific coordinate system.
Reference frame	A reference frame is one among many possible realizations of a reference system. It is characterized by a set of reference points from geodetic networks and a reference epoch.

Introduction

The historical definition of geodesy was given by F. R. Helmert (1880): “Geodesy is the science of measuring and mapping of Earth’s surface.” According to this definition, the task of geodesy is expressed in Torge (2003): “The task of geodesy is to determine the figure and the external gravity field of the Earth and other objects in space as functions of time by surface- or spacebased observations.”

Therefore, geodesy deals with measurements and representation of Earth’s geometry and its gravitational field and geodynamic phenomena (Earth rotation, Earth tides, and

crustal motion) in three-dimensional and time-varying space. Metrology defines the physical units, which are needed in geodesy. The measurements are related to various geodetic instruments and different methods. Earth-bound instruments are mostly operated in global networks, while a space-borne instrument senses the entire Earth while in orbit. Earth models contain a mathematical description approximating the physical reality in which observation data are modeled. The description of Earth's figure and its external gravity field requires the definition of reference systems, which are constituted by measurements.

As it is very difficult to fix a static and very precise global coordinate system to the continuously changing Earth, a permanent monitoring of reference positions in geodetic networks is necessary. These permanent observing networks, in which fundamental stations for geodesy have an indispensable role, are the bases for global geodetic reference frames. Such reference frames are the backbone for a better understanding of the system Earth, for any kind of geoinformation systems, and for space exploration (Hase 1999).

Geodetic Reference Systems

Theory of Reference Systems

In geodesy, the terms *reference system* and *reference frame* have different meanings: A reference system is based on physical theories and reflects an ideal idea. A reference frame is one among many possible realizations of a reference system and based on geodetic observations and hence available to users.

Example: A global reference system can be defined in such a way that the origin of the coordinate system coincides with the center of mass. The center of mass is an abstract physical model and not accessible as reference point. However, geodetic observations of satellite orbits are useful to realize a corresponding reference frame because the center of mass of Earth coincides with one of the two foci of the elliptical orbit of the satellite. The used data set of observations delivers one particular reference frame with respect to the definition of the reference system.

Reference systems are standardized by the introduction of conventional reference systems which are based on the decisions of international committees. These conventional reference systems become available to users by conventional reference frames (Schneider 1999). Reference frames are always based on observation data, which are processed with introduced hypotheses of the used reduction models. Due to the arbitrary settings in the processing of observation data, the defined ideal of a reference system can only be approximated with different analysis strategies. This circumstance and the need for comparison call for a standardization of reduction models in order to compare consistently different reference

frames. The International Earth Rotation and Reference Systems Service (IERS) provides the IERS Conventions for the standardization of physical constants and models with respect to global reference frames (IERS 2010)

Two reference systems are of importance in global geodesy: (a) the barycentric space-bound celestial reference system (CRS) and (b) the geocentric Earth-bound terrestrial reference system (TRS). While the first system is related to distant objects in space, the latter one is related to terrestrial reference points or to reference points in the near-Earth space. Both systems are tied by the Earth rotation parameters (EOP).

The figure of Earth is approximated by Earth models. The geometric models are spherical or ellipsoidal, while the geophysical models are based on expansion of the spherical harmonic functions in order to model the geoid as an equipotential reference surface. In an ideal situation, models of both categories coincide with their origins and have parallel main axes.

Metrology

Geodetic measurements in the domains of space, time, and gravity field refer to physical units of the SI (Système International). In general the modeling of space geodetic measurements in Newtonian space-time shows deficiencies. The underlying physical model for the definition of physical units must be based on the theory of general relativity (Damour et al. 1991). This requires that the physical units are defined in infinitesimal small spatial areas with only local and not global validity. The question is whether physical units defined in local laboratory space can be used on the global scale for space geodesy.

The units for time scale, spatial scale, and gravitational potential cannot be defined independently from the object to be measured. The metrological units are only defined as precisely as the measurements of the geodynamic phenomena interacting with the laboratory and vice versa (Hase 1999).

The introduction of the constant of the speed of light, $c = 299,792,458$ m/s, enables the introduction of the physical units *meter* and *second* and a method to measure space-time intervals if the synchronization of two local clocks fulfills the Einstein synchronization condition. Generally this condition is not fulfilled on Earth. Therefore, the spatial distance of the clocks must be defined in relation to the desired resolution of the measurement in order to neglect the spatial curvature effects.
